Abstract

CLC chloride/proton exchangers may support acidification of endolysosomes and raise their luminal Cl⁻ concentration. Disruption of endosomal CIC-3 causes severe neurodegeneration. To assess the importance of CIC-3 Cl⁻/H⁺ exchange, we now generate *Clcn3^{unc/unc}* mice in which CIC-3 is converted into a Cl⁻ channel. Unlike *Clcn3^{-/-}* mice, *Clcn3^{unc/unc}* mice appear normal owing to compensation by CIC-4 with which CIC-3 forms heteromers. CIC-4 protein levels are strongly reduced in *Clcn3^{-/-}*, but not in *Clcn3^{unc/unc}* mice because CIC-3^{unc} binds and stabilizes CIC-4 like wild-type CIC-3. Although mice lacking CIC-4 appear healthy, its absence in *Clcn3^{unc/unc}/Clcn4^{-/-}* mice entails even stronger neurodegeneration than observed in *Clcn3^{-/-}* mice. A fraction of CIC-3 is found on synaptic vesicles, but miniature postsynaptic currents and synaptic vesicle acidification are not affected in *Clcn3^{unc/unc}* or *Clcn3^{-/-}* mice before neurodegeneration sets in. Both, Cl⁻/H⁺-exchange activity and the stabilizing effect on CIC-4, are central to the biological function of CIC-3.

Introduction

Ion homeostasis of intracellular organelles like endosomes, lysosomes, and synaptic vesicles (SVs) is important for luminal enzyme activity, ligand–receptor interactions, transmembrane voltage,

transport of neurotransmitters, and other substrates across their limiting membranes, as well as vesicle budding, fusion, and trafficking. To date, most studies concentrated on luminal pH that drops along the endosomal/lysosomal pathway. This acidification is driven by the proton pump activity of V-type ATPases that need a neutralizing counter current. This current is believed to be carried mainly by chloride ions, although acidification of lysosomes prominently depends on cation channels (Steinberg *et al*, 2010; Weinert *et al*, 2010). The Cl⁻-dependent shunt was previously thought to be mediated by CLC Cl⁻ channels (Günther *et al*, 1998; Piwon *et al*, 2000; Kornak *et al*, 2001), but the vesicular CIC-3 to CIC-7 proteins, in contrast to the plasma membrane Cl⁻ channels (CIC-1, CIC-2, and CIC-K), are rather 2Cl⁻/H⁺-exchangers (Picollo & Pusch, 2005; Scheel *et al*, 2005; Neagoe *et al*, 2010; Weinert *et al*, 2010; Leisle *et al*, 2011; Rohrbough *et al*, 2018). Both, CLC channels and exchangers function as dimers with two independent ion permeation pathways that are entirely contained within each CLC monomer (Ludewig *et al*, 1996; Middleton *et al*, 1996; Weinreich & Jentsch, 2001; Dutzler *et al*, 2002; Zdebik *et al*, 2008; Jentsch & Pusch, 2018).

The physiological importance of vesicular CLCs is highlighted by mouse models and patients carrying *CLCN* mutations. Their pathologies range from impaired renal endocytosis and kidney stones (CIC-5) (Lloyd *et al*, 1996; Piwon *et al*, 2000; Wang *et al*, 2000) to severe neurodegeneration (CIC-3) (Stobrawa *et al*, 2001), intellectual disability and epilepsy (CIC-4) (Veeramah *et al*, 2013; Hu *et al*, 2016; Palmer *et al*, 2018), to lysosomal storage disease (CIC-6) (Poët *et al*, 2006) or osteopetrosis associated with lysosomal storage and neurodegeneration (CIC-7) (Kornak *et al*, 2001; Kasper *et al*, 2005). A gain-of-function mutation in *CLCN7* causes lysosomal storage disease and hypopigmentation without osteopetrosis (Nicoli *et al*, 2019).

Not only Cl⁻ channels, but also electrogenic 2Cl⁻/H⁺-exchangers are able to shunt proton pump currents. Indeed, the 2Cl⁻/H⁺-exchanger CIC-5 may support the acidification of renal endosomes (Günther *et al*, 2003; Hara-Chikuma *et al*, 2005a; Novarino *et al*,

2010) and CIC-7 is required to acidify the resorption lacuna of osteoclast (Kornak *et al*, 2001). However, more recent experiments demonstrate that the exchange activity, rather than the provision of an electrical shunt, is crucial for most biological roles of CIC-5 and CIC-7 (Novarino *et al*, 2010; Weinert *et al*, 2010). *Cln5^{unc}* and *Cln7^{unc/unc}* knock-in mice which carry uncoupling point mutations in the “gating glutamate”, a pore residue critically involved in $2\text{Cl}^-/\text{H}^+$ -exchange (Accardi & Miller, 2004), revealed that the conversion of $2\text{Cl}^-/\text{H}^+$ -exchange into a pure Cl^- conductance causes similar pathologies as the disruption of *Cln5* and *Cln7*, respectively (Novarino *et al*, 2010; Weinert *et al*, 2010). Comparable uncoupling mutations in *CLCN5* were subsequently identified in patients with Dent’s disease (Sekine *et al*, 2014; Bignon *et al*, 2018). These observations suggest an important role for proton-driven endosomal-lysosomal Cl^- accumulation. Indeed, lysosomal Cl^- concentration, but not luminal pH, was reduced in both *Cln7^{-/-}* and *Cln7^{unc/unc}* mice (Weinert *et al*, 2010).

The transport properties of CIC-3 had been highly controversial (for review, see (Jentsch, 2008; Jentsch & Pusch, 2018)), but it is now established that CIC-3 is a vesicular $2\text{Cl}^-/\text{H}^+$ -exchanger (Matsuda *et al*, 2008; Guzman *et al*, 2013; Jentsch & Pusch, 2018; Rohrbough *et al*, 2018) like the close homologs CIC-4 and CIC-5 (Picollo & Pusch, 2005; Scheel *et al*, 2005) and the other vesicular CLCs. In addition to its presence on endosomes, CIC-3 may also be found on SVs (Stobrawa *et al*, 2001; Salazar *et al*, 2004; Seong *et al*, 2005; Grønberg *et al*, 2010) and synaptic-like microvesicles (SLMVs) of neuroendocrine cells (Salazar *et al*, 2004; Maritzen *et al*, 2008). However, more recent work questioned a significant presence of CIC-3 on SVs (Schenck *et al*, 2009). Furthermore, these authors suggested that the reduced acidification of SVs from *Cln3^{-/-}* mice (Stobrawa *et al*, 2001) rather results from a secondary decrease in the vesicular glutamate transporter VGLUT1 which may also conduct chloride (Schenck *et al*, 2009).

We now asked whether the biological role of CIC-3 depends on its Cl^-/H^+ exchange activity or on its electrical conductance and whether CIC-3 is important for SV function. In stark contrast to the severe neurodegeneration of *Cln3^{-/-}* mice (Stobrawa *et al*, 2001; Dickerson *et al*, 2002; Yoshikawa *et al*, 2002), newly generated *Cln3^{unc/unc}* mice carrying an uncoupling mutation in CIC-3 lacked detectable phenotypes. This could be explained by a compensation by CIC-4 with which CIC-3 forms heteromers *in vivo*. Disruption of CIC-3 leads to increased ER retention and degradation of CIC-4, suggesting that a reduction of CIC-4 levels contributes to the severe neurodegeneration of *Cln3^{-/-}* mice. We also demonstrated that CIC-3 is expressed on a fraction of SVs and that miniature postsynaptic currents and SV acidification were not affected in young *Cln3^{-/-}* mice before the onset of neurodegeneration. Proton-driven Cl^- transport by CIC-3, if not compensated by CIC-4, is crucial for the integrity of the CNS. CIC-3 overwhelmingly localizes to endosomes and apparently has no significant role in SVs.

Results

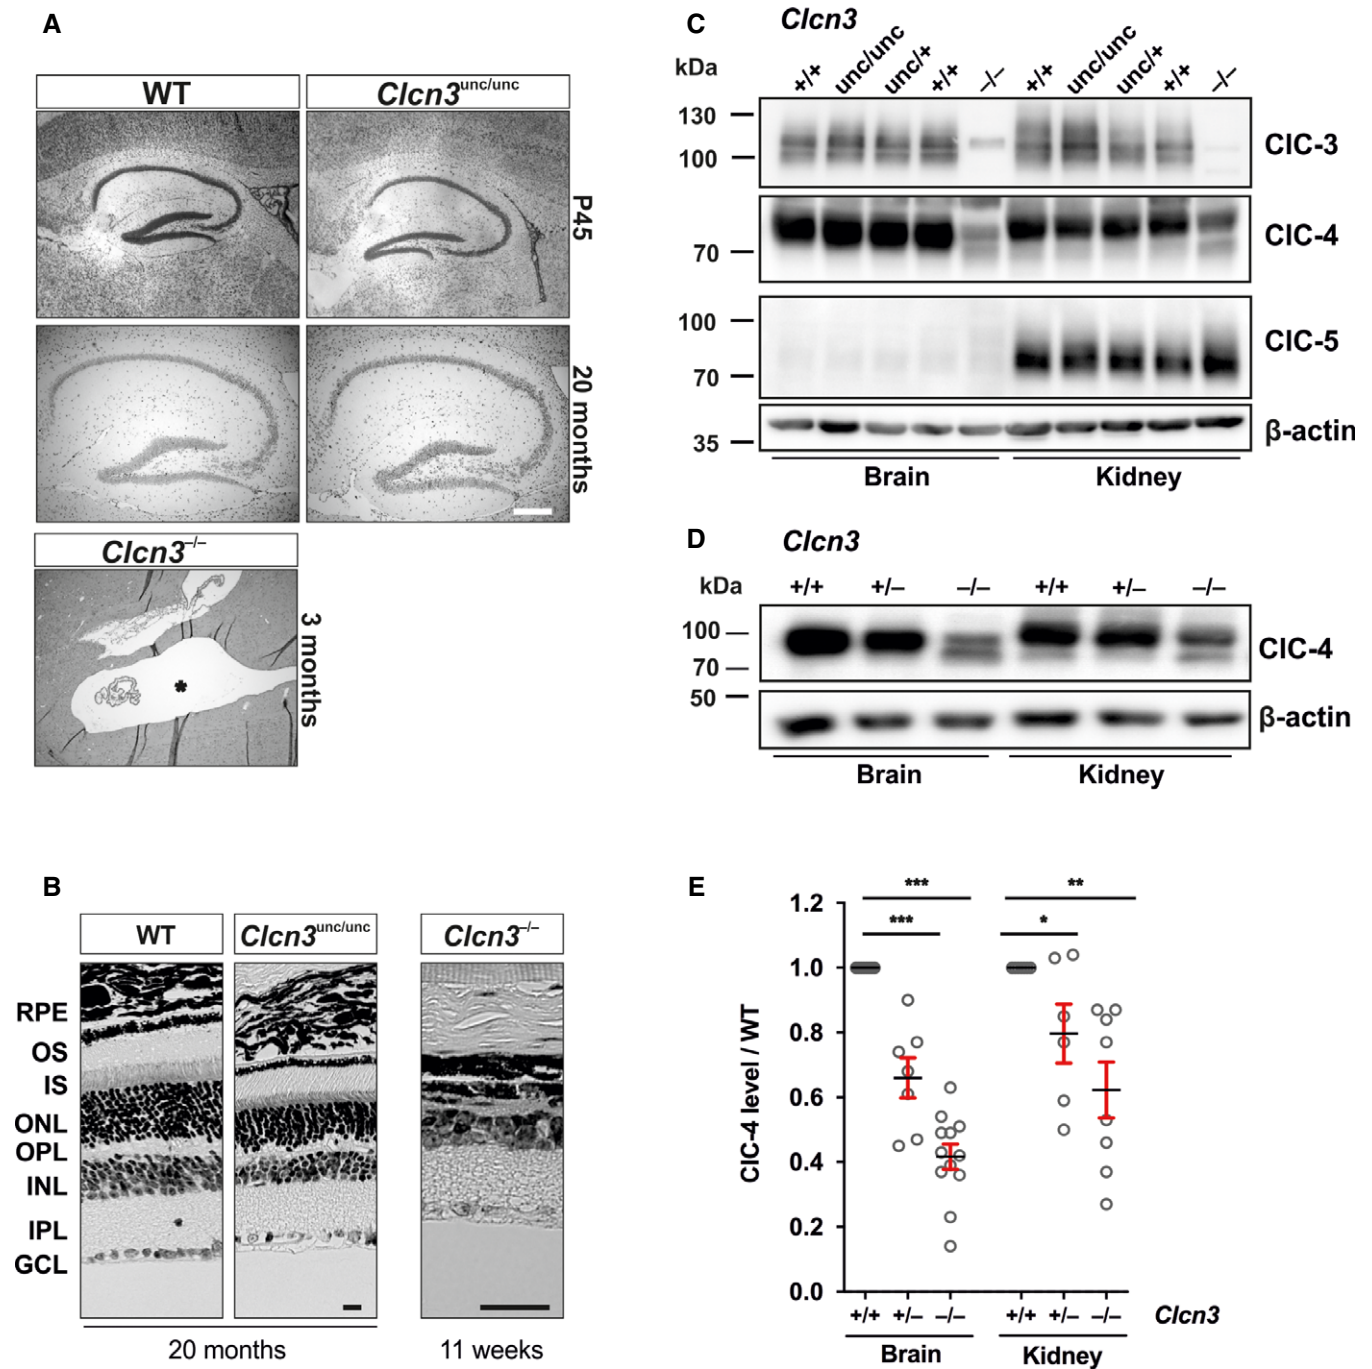

Cln3^{unc/unc} mice do not display neurodegeneration

To elucidate whether the electrical conductance or the Cl^-/H^+ -exchange activity of CIC-3 is crucial for its biological role, we

generated *Cln3^{unc/unc}* knock-in mice carrying the E224A mutation in the “gating glutamate” (Appendix Fig S1A–D). When studied in a CIC-3 construct that partially localizes to the plasma membrane (Zhao *et al*, 2007) (Fig EV1A), this mutation linearized the normally strongly outwardly rectifying CIC-3 currents (Fig EV1B and C). As previously observed with the bacterial ecCIC exchanger (Accardi & Miller, 2004) and mammalian CIC-4 through CIC-7 (Picollo & Pusch, 2005; Scheel *et al*, 2005; Neagoe *et al*, 2010; Leisle *et al*, 2011), this mutation also uncouples Cl^- currents from H^+ countertransport (Rohrbough *et al*, 2018). “Uncoupled” CLC exchangers mediate channel-like Cl^- conductances without appreciable transport of H^+ . *Cln3^{unc/unc}* mice were viable and expressed the mutant CIC-3^{unc} protein at wild-type (WT) levels (Appendix Fig S1E). These mice were born at Mendelian ratios, were fertile, and had no obvious phenotype. Even at 20 months of age, they neither displayed the severe degeneration of the CNS nor of the retina (Fig 1A and B) that is observed in *Cln3^{-/-}* mice (Stobrawa *et al*, 2001; Dickerson *et al*, 2002; Yoshikawa *et al*, 2002). This contrasts with findings for *Cln5^{unc}* and *Cln7^{unc/unc}* mice (Novarino *et al*, 2010; Weinert *et al*, 2010) which phenotypically largely resemble the respective null mice (Piwon *et al*, 2000; Kornak *et al*, 2001). These observations raised the possibility that another vesicular CLC protein might compensate for the loss of CIC-3 $2\text{Cl}^-/\text{H}^+$ -exchange in *Cln3^{unc/unc}*, but not in *Cln3^{-/-}* mice.

CIC-4 levels are reduced in *Cln3^{-/-}*, but not in *Cln3^{unc/unc}* mice

We therefore examined the expression levels of CIC-4 and CIC-5, the closest homologs of CIC-3 (~76% identity), in tissues of *Cln3^{unc/unc}* and *Cln3^{-/-}* mice. Although CIC-4 mRNA levels are not changed in the brain of *Cln3^{-/-}* mice (Stobrawa *et al*, 2001), CIC-4 protein levels were strongly and more moderately decreased in brain and kidney of *Cln3^{-/-}* mice, respectively (Fig 1C–E). Depending on the tissue and experimental conditions, the CIC-4 band often appeared as doublet in *Cln3^{-/-}* mice (Fig EV2B). Western blot quantifications of the upper band, which likely reflects the mature glycosylated form of CIC-4 (see below), revealed that it was reduced down to 30 and 60% in brain and kidney of *Cln3^{-/-}* mice, respectively (Fig 1E). In heterozygous *Cln3^{+/-}* mice, CIC-4 protein amounts were reduced down to ~65% in brain and ~80% in kidney (Fig 1C and D). Expression of CIC-5, which is found in kidney but is almost absent from brain, appeared unchanged upon *Cln3* disruption (Fig 1C). CIC-4 protein levels were markedly reduced in all other *Cln3^{-/-}* tissues examined, including liver, pancreas, adrenal gland, spleen, lung, skeletal muscle, and heart (Fig EV2B). Treatment with PNGase F, which removes all N-linked glycans, showed that differences in size of CIC-4 were due to differential glycosylation (Fig EV2C). In contrast to the larger CIC-4 species, the lower band, which was much more prominent in most *Cln3^{-/-}* tissues, was sensitive to digestion with Endo H that cleaves oligosaccharides of core-glycosylated ER-resident membrane proteins (Fig EV2D). This indicated that in *Cln3^{-/-}* mice, a sizeable portion of CIC-4 does not leave the ER, where it is subject to degradation. Importantly, no reduction of CIC-4 protein levels was observed in brain or kidney of *Cln3^{unc/unc}* mice (Figs 1C and EV2A) which express an “uncoupled”, but otherwise intact CIC-3 protein. Importantly, whereas CIC-4 levels depended on CIC-3, CIC-3 levels were unchanged in both brain and kidney of *Cln4^{-/-}* mice (Fig EV2A).

Figure 2. Formation of CIC-3/CIC-4 heteromers.

A Co-immunoprecipitation reveals a CIC-3–CIC-4 complex. Ten percent of solubilized brain membranes of WT and *Clcn3^{unc/unc}* mice were directly loaded on the gel (input, or first immunoprecipitated (IP) with antibodies against CIC-3 or CIC-4). Western blots were probed for CIC-3 and CIC-4. Equivalent amounts of lysates and precipitates were loaded. * unspecific band/contamination.

B FRET experiments show homo- and heteromerization of CIC-3 and CIC-4 constructs [fused to yellow fluorescent protein (YFP) and cyan fluorescent protein (CFP)] overexpressed in COS-7 cells. Co-expressed constructs are indicated. Graph represents energy transfer efficiencies from acceptor photobleaching, depicted as bleach corrected values (subtraction of CIC-4CFP alone). Mean values \pm SEM. *N* = 20 (CIC-3YFP/CIC-4CFP); 33 (CIC-3YFP/CIC-3CFP); 26 (CIC-4YFP/CIC-4CFP); 42 (CIC-3YFP/Lamp-1CFP) cells. *****P* < 0.0005 (two-tailed unpaired *t*-test).

C Immunolabeling shows subcellular localization of hCIC-4 (top, green in merge), hCIC-3 (middle, green in merge), and hCIC-3^{unc} (bottom, green in merge) of transiently transfected COS-7 cells, in comparison with either PDI or Lamp-1 (both red) as marker for the ER and late endosomes/lysosomes, respectively.

D Co-localization of hCIC-3 and hCIC-4 in cytoplasmic vesicles of COS-7 cells transfected with hCIC-4 cDNA [hemagglutinin (HA) tagged] together with either hCIC-3 or hCIC-3^{unc}. Immunostaining used antibodies against CIC-3 and HA tag (green and red in merge, respectively).

Data information: DNA stained with DAPI in (C) and (D), [scale bar in (C) and (D): 20 μ m].

1996; Weinreich & Jentsch, 2001; Mohammad-Panah *et al*, 2003; Suzuki *et al*, 2006; Guzman *et al*, 2017). We therefore suspected that CIC-3 stabilizes CIC-4 by forming heterodimers *in vivo*. Indeed, CIC-3 antibodies co-immunoprecipitated CIC-4 from both WT and *Clcn3^{unc/unc}* brain and vice versa (Fig 2A). These results were corroborated by Förster resonance energy transfer (FRET) measurements with fluorescently tagged CIC-3 and CIC-4 in transfected COS-7 cells (Fig 2B). Agreeing with previous results obtained with over-expressing HEK cells (Okkenhaug *et al*, 2006; Guzman *et al*, 2017), CIC-4 showed typical ER-like reticular staining when expressed in COS-7 cells (Fig 2C). In contrast, CIC-3 localized to vesicular structures, which were partially positive for the late endosomal/lysosomal marker Lamp-1 (Fig 2C). When both CLCs were co-transfected, CIC-4 co-localized with CIC-3 in vesicles (Fig 2D) (Guzman *et al*, 2017). A similar change in CIC-4 localization was observed upon co-expression with the CIC-3^{unc} mutant (Fig 2D), as expected from our observation that the mutant CIC-3 protein retains its physical interaction with CIC-4 (Fig 2A). Hence, both WT CIC-3 and CIC-3^{unc} associate with CIC-4 and thereby promote the transport of CIC-4 from the ER to endosomal–lysosomal compartments and protects it from degradation.

Severe neurodegeneration in *Clcn3^{unc/unc}/Clcn4^{-/-}* mice

The above experiments suggested that CIC-4 may compensate for a loss of CIC-3 function in *Clcn3^{unc/unc}*, but not in *Clcn3^{-/-}* mice in which brain CIC-4 levels are decreased to ~ 30% of WT (Fig 1E). To completely eliminate this potential compensation, we crossed *Clcn3^{unc/unc}* mice with *Clcn4^{-/-}* mice. Although *Clcn4^{-/-}* mice appear to be normal (Rickheit *et al*, 2010), we reassessed potential effects of *Clcn4* disruption because mutations in *CLCN4* were recently associated with X-linked intellectual disability and epileptic encephalopathy (Veeramah *et al*, 2013; Hu *et al*, 2016; Palmer *et al*,

CIC-3 and CIC-3^{unc} heteromerize with CIC-4

CLC proteins function as dimers (Ludewig *et al*, 1996; Middleton *et al*, 1996; Dutzler *et al*, 2002). With the exception of CIC-6 and CIC-7, heterodimers have been observed upon heterologous co-expression of members of the same homology branch (Lorenz *et al*,

Figure 3. Life span and neurodegeneration of *Clcn3/Clcn4* mouse models.

A $Clcn3^{unc/unc}/Clcn4^{-/-}$ and $Clcn3^{-/-}$ mice died within 3–4 weeks after birth. Approximately 20% of the animals survived in either line ($Clcn3^{unc/unc}/Clcn4^{-/-}$, $n = 136$, and $Clcn3^{-/-}$, $n = 187$). All $Clcn3^{-/-}/Clcn4^{-/-}$ mice ($n = 4$) died within 1–2 weeks after birth.

B Nissl-stained paraffin sections show progressive neuronal cell loss (arrows) that begins in hippocampal CA1 region of P14 $Clcn3^{unc/unc}/Clcn4^{-/-}$ mice and results in a complete loss of the hippocampus at P28. Neurodegeneration progresses slower in $Clcn3^{-/-}$ mice (Stobrawa et al, 2001) (scale bar: 200 μ m).

C Semi-thin sections of P28 retinæ revealed degeneration of photoreceptor cells in the outer nuclear layer and outer and inner segment of $Clcn3^{unc/unc}/Clcn4^{-/-}$, but not of $Clcn3^{unc/unc}$ or $Clcn4^{-/-}$ mice (scale bar: 50 μ m). GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; IS, photoreceptor inner segments; ONL, outer nuclear layer; OPL, outer plexiform layer; OS, photoreceptor outer segments; RPE, retinal pigment epithelium.

Source data are available online for this figure.

5 weeks after birth and only ~20% became older than 10 weeks (Fig 3A). Brains from $Clcn3^{unc/unc}/Clcn4^{-/-}$ mice displayed severe neurodegeneration (Fig 3B). Like in $Clcn3^{-/-}$ mice (Stobrawa et al, 2001), degeneration became first apparent in the hippocampus, but progressed much faster. Whereas the hippocampus began to show mild degeneration at P21 and almost totally disappeared at 10 weeks of age in $Clcn3^{-/-}$ mice (Stobrawa et al, 2001), $Clcn3^{unc/unc}/Clcn4^{-/-}$ mice showed severe hippocampal degeneration at P21 and mice had lost their hippocampi already 4 weeks after birth (Fig 3B). Again similar to $Clcn3^{-/-}$ mice, neurodegeneration in $Clcn3^{unc/unc}/Clcn4^{-/-}$ mice was accompanied by an activation of astrocytes as indicated by GFAP staining. $Clcn3^{unc/unc}/Clcn4^{-/-}$ mice showed severe retinal degeneration (Fig 3C), similar to $Clcn3^{-/-}$ mice (Stobrawa et al, 2001).

The more severe phenotype of $Clcn3^{unc/unc}/Clcn4^{-/-}$ compared to $Clcn3^{-/-}$ mice suggested that the severity of neurodegeneration depends on the expression levels of CIC-4. $Clcn3^{unc/unc}/Clcn4^{+/-}$ mice, in which CIC-4 protein levels are reduced to 75% of normal, did not show neurodegeneration even at 12 weeks of age (Appendix Fig S3A). Likewise, on a $Clcn4^{-/-}$ background, heterozygous $Clcn3^{unc}$ alleles did not cause pathologies (Appendix Fig S3B). In contrast, only very few $Clcn3^{-/-}/Clcn4^{-/-}$ mice were born and then died shortly after birth (Fig 3A). Hence, CIC-3 and CIC-4 have partially overlapping functions. The occurrence of neurodegeneration in $Clcn3^{-/-}$, but not $Clcn4^{-/-}$ mice might be largely explained by the fact that CIC-4 levels are strongly decreased in $Clcn3^{-/-}$ mice, whereas CIC-3 abundance does not depend on CIC-4. As revealed only in the absence of CIC-4, the pure Cl^{-}/H^{+} -exchange of WT CIC-3 cannot functionally replace the $2Cl^{-}/H^{+}$ -exchange of WT CIC-3. However, this conductance may substitute for some aspect of CIC-3 function as revealed by the milder phenotype of $Clcn3^{unc/unc}/Clcn4^{-/-}$ compared to $Clcn3^{-/-}/Clcn4^{-/-}$ mice. However, we cannot exclude that the more severe phenotype of the double knock-out is in part owed to the lack of the CIC-3 protein that might bind to unknown interaction partners.

Subcellular localization of CIC-3 and CIC-4 in brain

Because available CIC-3 antibodies are of limited use for immunohistochemistry (IHC) of native tissue, we generated knock-in mice in which we epitope-tagged CIC-3 (Appendix Fig S4A and B). We

2018). However, $Clcn4^{-/-}$ mice neither displayed discernible anatomical changes in the brain (Appendix Fig S2), nor obvious behavioral abnormalities.

$Clcn3^{unc/unc}/Clcn4^{-/-}$ mice were born at Mendelian ratio. Similar to $Clcn3^{-/-}$ mice (Stobrawa et al, 2001; Dickerson et al, 2002; Yoshikawa et al, 2002), they were growth-retarded. Most died within

opted for a Venus tag (ven), a fast-maturing and brightly fluorescent variant of the green fluorescent protein (GFP) (Nagai *et al*, 2002), which we fused to the N-terminus of CIC-3. Homozygous *Clcn3*^{ven/ven} mice were born at Mendelian ratio, had a normal life expectancy and did not show neurodegeneration even at 10 weeks of age (Appendix Fig S4C). *Clcn3*^{ven/ven}/*Clcn4*^{-/-} mice did not display hippocampal degeneration either (Appendix Fig S4C), suggesting that the ^{Venus}CIC-3 fusion protein functions normally. ^{Venus}CIC-3 protein levels were undistinguishable from CIC-3 levels in WT mice (Appendix Fig S4D). Since low fluorescence intensities precluded direct imaging of ^{Venus}CIC-3 fluorescence in tissue sections, we used anti-GFP antibodies in IHC. In brain, ^{Venus}CIC-3 was most prominently expressed in the hilus and stratum lucidum of the hippocampus and in the cerebellum (Appendix Fig S5A and B). IHC for CIC-4 revealed a similar distribution (Appendix Fig S5C). The absence of signals for ^{Venus}CIC-3 and CIC-4 in tissue from WT and *Clcn4*^{-/-} mice, respectively, validated the specificity of our labeling (Appendix Figs S5B and C, and Fig 4A).

Compatible with the formation of CIC-3/4 heteromers *in vivo*, ^{Venus}CIC-3 and CIC-4 co-localized in punctate pattern in cell bodies and neurites of hippocampal pyramidal neurons (Fig 4B). Both in brain sections and in cultured hippocampal neurons of *Clcn3*^{ven/ven} mice, CIC-3 localized to compartments that were positive for the endosomal marker EEA1 or for Lamp-1, a marker of late endosomes and lysosomes (Fig 4C and D). Roughly 30, 20, and 10% of ^{Venus}CIC-3-positive structures in somata of cultured hippocampal neurons were co-labeled for transferrin receptor (TfR), EEA1, and Lamp-1, respectively (Appendix Fig S6). We also found ^{Venus}CIC-3 in astrocytes and oligodendrocytes (Fig EV3A) where it co-localized with rab4, EEA1, and TfR, but not significantly with Lamp-1 (Fig EV3B). Neither VGLUT1 nor synaptophysin, both markers for SVs, showed significant co-localization with CIC-3 (Fig 4C and D).

However, CIC-3 was described to also localize to SVs (Stobrawa *et al*, 2001; Salazar *et al*, 2004; Seong *et al*, 2005; Grønberg *et al*, 2010) and SLMVs (Salazar *et al*, 2004; Maritzen *et al*, 2008) and to affect synaptic physiology (Wang *et al*, 2006; Riazanski *et al*, 2011; Guzman *et al*, 2014). Based on comparisons of CIC-3 with VGLUT1 levels in quantitative Western blots, however, Schenck *et al* (2009) reported that CIC-3 was present on only every 2,000th SV. We therefore re-examined this important issue. Immunoblots detected CIC-3 and CIC-4 in the LP2 fraction of brain membranes, which is enriched for SVs as indicated by the accumulation of synaptophysin (Fig EV4A and B) and the virtual absence of postsynaptic PSD95 (Fig EV4A). Using our KO-controlled CIC-3 antibody (Stobrawa *et al*, 2001) and a VGLUT1 construct that was epitope-tagged at the N-terminus for antibody calibration, quantitative Western blot analysis suggested that the copy number ratio of CIC-3/VGLUT1 in the LP2 fraction is ~ 1/250 (Fig EV4C–E). This value is much higher than the CIC-3/VGLUT1 ratio of ~ 1/5,000 in the SV fraction reported by Schenck *et al* who have used a similar approach but had tagged VGLUT1 at the C-terminus. Taking into account the typical SV content of the LP2 fraction (~ 50%) (Huttner *et al*, 1983) and the number of VGLUT1 on SVs (~ 10) (Takamori *et al*, 2006), our results yielded the rough estimate of one CIC-3 protein on every 25th SV (Fig EV4C–E). The expression of CIC-3 on endosomes, the presence of endosomal structures in synaptic boutons (Watanabe *et al*, 2014; Milosevic, 2018), and the presence of the endosomal marker

rab4 and lysosomal cathepsin D in LP2 fractions (Fig EV4B) suggest that the abundance of CIC-3 on SVs might even be lower.

We further examined the presence of CIC-3 on SVs by single-vesicle imaging (Farsi *et al*, 2016). Venus-tagged SVs purified from brain of *Clcn3*^{ven/ven} mice (Fig 4E) were immobilized on coated glass cover slips at low density and imaged using total-internal reflection fluorescence (TIRF) microscopy (Fig 4F). The well-separated vesicles allowed to correlate the expression of CIC-3 with those of the SV marker proteins synaptophysin or VGLUT1 by immunofluorescence (IF). Roughly 10% of vesicles stained for either VGLUT1 or synaptophysin showed Venus-CIC-3 fluorescence (Fig 4G). This value may underestimate the proportion of SVs containing CIC-3 since the procedures needed to detect VGLUT1 and synaptophysin by IF affected Venus fluorescence. Sixty and eighty percent of Venus-CIC-3 containing vesicles were labeled for VGLUT1 or synaptophysin, respectively (Fig 4H and I), suggesting that the remainder might represent GABAergic SVs or endosome-like vesicles.

Collectively, these data show that CIC-3 is present on a considerably larger fraction of SVs than reported by Schenck *et al* (2009). Although both types of experiments (Figs EV4 and 4F–H) gave quantitatively different results, they suggest that maybe 5–15% of SVs contain CIC-3. As indicated by IHC of brain sections, however, the bulk of CIC-3 is rather found on endosomes.

Acidification of synaptic vesicles and neuronal endosomes

CIC-3 was reported to support the acidification of endosomes (Yoshikawa *et al*, 2002; Hara-Chikuma *et al*, 2005b; Weylandt *et al*, 2007) and SVs (Stobrawa *et al*, 2001; Riazanski *et al*, 2011) by providing an electric shunt for proton pumping. However, more recent work (Schenck *et al*, 2009) suggested that impaired SV acidification in *Clcn3*^{-/-} mice may rather be due to the observed reduction in the levels of VGLUT1 (Stobrawa *et al*, 2001), which, in addition to its role as glutamate transporter, may also conduct Cl⁻ (Schenck *et al*, 2009; Preobraschenski *et al*, 2014; Eriksen *et al*, 2016; Martineau *et al*, 2017).

Since the impairment of SV acidification in *Clcn3*^{-/-} mice may be age-dependent (Schenck *et al*, 2009), expression levels of CIC-3, CIC-4, and key synaptic proteins in the brain of WT and *Clcn3*^{-/-} mice were examined as function of age (Fig 5A). In WT mice, CIC-3 and CIC-4 expression remained constant over the time span investigated (2–12 weeks), as did the changes in CIC-4 observed in *Clcn3*^{-/-} mice (Figs 1C–E and 5A). Protein levels of the vesicular GABA transporter VGAT, the α 1 subunit of the GABA_A receptor, and the GluR4 subunit of the glutamate receptor did not change with age and were not affected by *Clcn3* disruption. By contrast, VGLUT1 expression markedly increased between 2 and 6 weeks of age, whereas VGLUT2 levels declined over the entire time span. In line with our previous observations (Stobrawa *et al*, 2001), VGLUT1 levels were markedly reduced compared to WT in 6- and 12-week-old *Clcn3*^{-/-} mice (Fig 5A) which already display overt neurodegeneration (Stobrawa *et al*, 2001).

ATP-driven luminal acidification of SV-enriched LP2 fractions was assessed by acridine orange quenching (Fig 5B). Correlating with the decrease of VGLUT1, *Clcn3* disruption decreased ATP-driven acidification of LP2 vesicles at 6 and 12, but not at 2 weeks of age (Fig 5C). LP2 fractions from either *Clcn3*^{unc/unc} or *Clcn4*^{-/-}

Figure 4. Subcellular localization of ^{Venus}CIC-3 and CIC-4 in neurons.

- A GFP antibodies immunolabel ^{Venus}CIC-3 (green) in the somata of CA1 pyramidal neurons of *Clcn3^{ven/ven}*, but not *Clcn3^{+/+}* brain sections. sp, stratum pyramidale (scale bar: 20 μ m).
- B Co-immunolabeling of ^{Venus}CIC-3 (green) with CIC-4 (red) in the CA3 region of *Clcn3^{ven/ven}* mice (scale bar: 20 μ m). sl, stratum lucidum; sp, stratum pyramidale.
- C Co-immunostaining of ^{Venus}CIC-3 (green) with EEA1 (red, left panel), Lamp-1 (red, middle panel), or synaptophysin (red, right panel) in either CA1 or CA3 region of *Clcn3^{ven/ven}* mice. Arrows indicate structures of overlap (scale bar: 5 μ m).
- D GFP antibody immunolabels ^{Venus}CIC-3 (green) in neurites of cultured neurons. EEA1 and VGLUT1 are co-stained (both in red; left and right panel, respectively). The dendritic marker MAP2 is stained in blue (right panel; scale bars: 10 μ m). DNA stained with DAPI.
- E Immunoblot analysis of fractions collected during preparation of SVs from brain of *Clcn3^{ven/ven}* mice. ^{Venus}CIC-3 (detected with GFP antibody) co-purified with SV marker protein synaptophysin.
- F Fluorescence of immobilized Venus-tagged SVs imaged with TIRF microscopy. Scale bar, 2 μ m.
- G, H Co-localization between the Venus-tagged vesicles with antibodies against VGLUT1 and synaptophysin was analyzed. (G) 11.4 ± 0.6 (SD) of VGLUT1-labeled SVs and 8.2 ± 2 (SD) of synaptophysin-labeled SVs showed Venus fluorescence ($n = 6$). (H) 65 ± 5.4 (SD) and 79.4 ± 3.8 (SD) of Venus-tagged SVs showed co-localization with VGLUT1 and synaptophysin, respectively ($n = 6$).
- I Co-immunolabeling of ^{Venus}CIC-3 (green) with synaptophysin (red) of immobilized SVs imaged with TIRF microscopy. Vesicle in quadrant delimited by dashed line is shown in higher magnification in merge. Scale bar, 2 μ m.

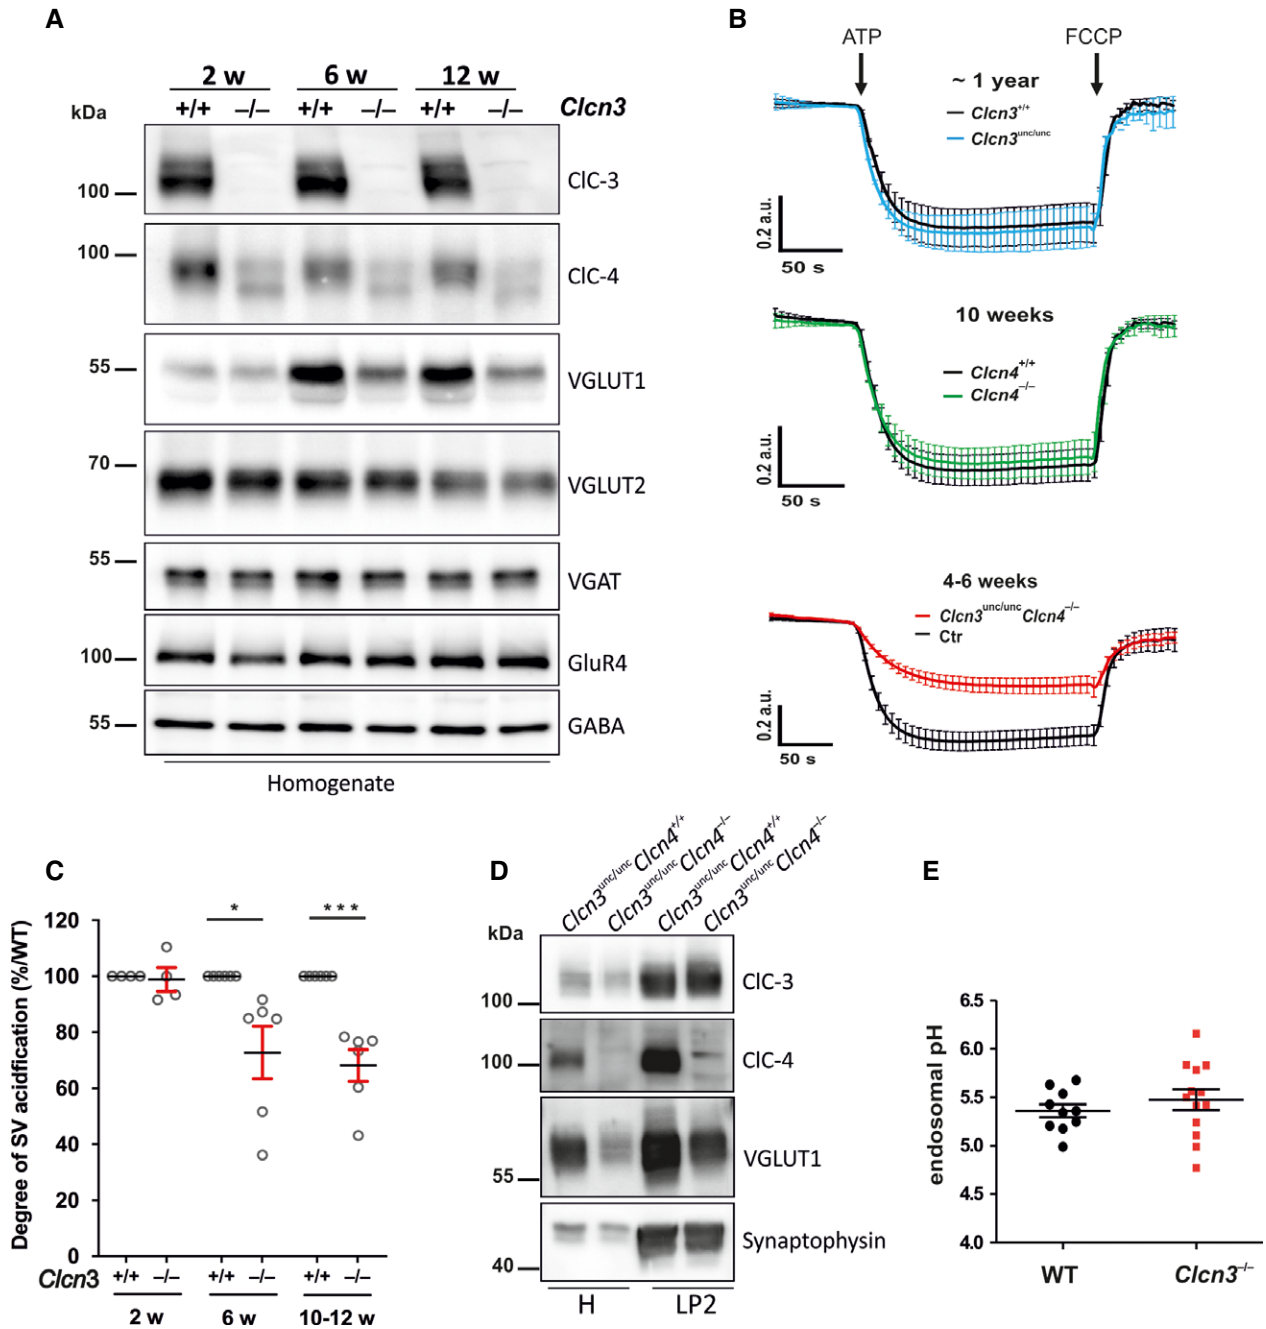

Figure 5. ATP-induced acidification of synaptic vesicle-enriched LP2 fraction derived from different *Clcn3* and *Clcn4* mouse models.

A Immunoblots for CIC-3, CIC-4, VGLUT1, VGLUT2, VGAT, GluR4, and GABA_A-R- α 1 of whole lysates from brain of *Clcn3*^{+/+} and *Clcn3*^{-/-} mice at 2, 6, and 12 weeks of age.

B Acidification of synaptic vesicle LP2 fractions from *Clcn3*^{unc/unc} and *Clcn3*^{+/+} mice at 1 year of age (upper panel, *n* = 2 animals each and \geq 3 measurements per animal), 10-week-old *Clcn4*^{-/-} and WT mice (middle panel, *n* = 3 animals each and \geq 3 measurements per animal), and 4- to 6-week-old *Clcn3*^{unc/unc}/*Clcn4*^{-/-} and control mice (lower panel, six animals each with \geq 2 measurements per animal). A decrease in fluorescence reflects acidification. The protonophore FCCP dissipated the pH gradient. Mean values \pm SEM.

C Quantification of ATP-induced acidification of LP2 fractions derived from 2, 6, and 10- to 12-week-old *Clcn3*^{-/-} compared to wild-type mice. Acidification measured by acridine orange fluorescence in the presence of 60 mM KCl. At least two animals in at least two independent experiments were pooled. Each measurement was performed at least three times. Mean \pm SEM is shown. **P* < 0.05, ****P* < 0.0005 (two-tailed unpaired *t*-test).

D Immunoblot revealed strong reduction of VGLUT1 levels in the homogenate (H) and LP2 fraction of *Clcn3*^{unc/unc}/*Clcn4*^{-/-} mice.

E Endosomal pH of *Clcn3*^{+/+} and *Clcn3*^{-/-} primary hippocampal neurons determined with a pH-sensitive transferrin conjugate. *N* = 5 independent cell lines with at least two live cell dishes per cell line with about 10 images each and \geq 10 Tfn-positive compartments per image and genotype were analyzed. Mean \pm SEM is shown.

Source data are available online for this figure.

mice, which do not show neurodegeneration, exhibited normal ATP-driven acidification. However, acidification of vesicles obtained from *Cln3^{unc/unc}/Cln4^{-/-}* mice with fast progressing neurodegeneration and strong reduction of VGLUT1 levels (Fig 5D) was markedly reduced even at 4–6 weeks of age when compared to control littermates (Fig 5B).

We also determined luminal pH of TfR-positive endosomal compartments in cultured neurons by ratiometric imaging. pH-sensitive and pH-insensitive transferrin-coupled conjugates Tfn-FITC and Tfn-546, respectively, were chased into recycling endosomes after endocytosis. Immunolabeling showed that roughly 80% of TfR-expressing compartments contained ^{Venus}CIC-3 (Appendix Fig S6). There was no significant difference in average pH between WT [5.36 ± 0.07 (SEM)] and *Cln3^{-/-}* endosomes (pH 5.48 ± 0.11 ; Fig 5E), suggesting that CIC-3 does not provide the main shunt conductance for the acidification of TfR-positive neuronal compartments.

Effect of CIC-3 on synaptic function and structure

The failure of *Cln3* disruption to impair SV acidification before the onset of neurodegeneration questioned a role of CIC-3 in loading SVs with neurotransmitters. Indeed, in our previous work (Stobrawa et al, 2001), *Cln3* disruption did not affect the amplitude or frequency of miniature inhibitory postsynaptic currents (mIPSCs) which are elicited by spontaneous exocytosis of GABA-containing SVs. We had only detected marginal effects on miniature excitatory (glutamatergic) postsynaptic currents (mEPSCs), which, however, may have been caused by incipient neurodegeneration at P13–P15, the time window of our experiments (Stobrawa et al, 2001). By contrast, Nelson and co-workers more recently reported markedly reduced frequencies and amplitudes of mIPSCs in *Cln3^{-/-}* mice (Riazanski et al, 2011) and Fahlke's group stated that *Cln3* disruption increased frequencies and amplitudes of mEPSCs in primary neuronal cultures (Guzman et al, 2014). We re-investigated mIPSCs and mEPSCs in CA1 hippocampal pyramidal neurons at P14–16, now including also *Cln3^{unc}* and *Cln4⁻* alleles (Fig 6A–G). Again no differences in mIPSCs between *Cln3^{-/-}* and *Cln3^{+/+}* mice were found (Fig 6A and B). We neither observed differences in mIPSCs between *Cln3^{unc/unc}* and *Cln3^{+/+}* mice (Fig 6C), nor between *Cln4^{+/+}* and *Cln4^{-/-}* mice (Fig 6D). Compared to *Cln4^{-/-}* mice, the mIPSC interevent intervals, but not amplitudes, appeared longer in *Cln3^{unc/unc}/Cln4^{-/-}* mice (Fig 6E). However, these mice have the most severe neurodegeneration among the investigated genotypes. In these mice, there also appeared to be a marginal increase in mEPSC frequency, but not amplitudes, when compared to *Cln4* mice (Fig 6F and G). Guzman et al (2014) reported that the area of SVs was increased by ~30% in *Cln3^{-/-}* versus WT mice. However, we did not observe significant changes either in the number nor the size of SVs and endosome-like vacuoles of glutamatergic spine synapses in *Cln3^{-/-}* compared to WT brain sections (Fig EV5).

We further investigated whether CIC-3 is exocytosed together with SV markers upon electrical stimulation of primary hippocampal neurons. These neurons were transfected with a construct in which the genetically encoded pH-sensitive indicator pHluorin (Miesenböck et al, 1998) was fused to a luminal loop of CIC-3 (CIC-3-pHluorin). The fluorescence of the fusion protein is expected to increase upon exocytosis from an acidic SV because it then faces the more alkaline extracellular medium. Subsequent endocytosis and

vesicular acidification again reduce fluorescence. pH-sensitive synaptobrevin 2-mOrange reported SV exocytosis. In contrast, co-transfected CIC-3-pHluorin fluorescence did not increase in response to action potential firing (Fig 6H), suggesting that exocytosis-competent SVs express only low amounts of CIC-3.

Discussion

The biological importance of particular ion transport processes is most impressively demonstrated by phenotypes resulting from their genetic manipulation in animal models, as reported here for CIC-3 and CIC-4. Our work demonstrates that the exchange of Cl⁻ for H⁺, rather than the provision of a conductance, is crucial for the biological role of CIC-3. This role became only apparent in the absence of CIC-4 because the exchange activity of CIC-4 (Picollo & Pusch, 2005; Scheel et al, 2005) compensated for the loss of CIC-3 Cl⁻/H⁺-exchange in *Cln3^{unc/unc}* mice in which CIC-3 mediates a Cl⁻ conductance. *In vivo*, the stability of CIC-4 depends on CIC-3 with which it forms heterodimers. The bulk of CIC-3 resides on endosomes and to a minor degree also on SVs. However, we could not confirm reports suggesting an important role of CIC-3 in synaptic physiology (Riazanski et al, 2011; Guzman et al, 2014).

Heteromeric CLCs

CLC Cl⁻ channels and transporters (Jentsch, 2008; Jentsch & Pusch, 2018) function as dimers with one permeation pathway per CLC monomer (Ludewig et al, 1996; Middleton et al, 1996; Weinreich & Jentsch, 2001; Dutzler et al, 2002). In addition to homodimers, some CLC proteins can form heterodimers (Lorenz et al, 1996; Mohammad-Panah et al, 2003; Suzuki et al, 2006; Guzman et al, 2017) which may display novel properties (Lorenz et al, 1996). It has remained unclear whether CLC heterodimers exist *in vivo* and whether they are biologically important. We found that *in vivo* a substantial portion of CIC-4 is found in physical association with CIC-3. Whereas CIC-3 reaches endosomes without CIC-4, the presence of CIC-4 in endosomes largely depends on CIC-3. In the absence of the CIC-3 binding partner, a large fraction of CIC-4 remains in the ER where it is probably degraded. As indicated by the even more severe pathology of *Cln3^{-/-}/Cln4^{-/-}* compared to *Cln3^{-/-}* mice, the reduced CIC-4 levels in *Cln3^{-/-}* mice likely contribute to their neurodegeneration (Stobrawa et al, 2001; Yoshikawa et al, 2002). The reason for the ER retention of CIC-4 remains unclear. Several membrane proteins display arginine-based retention motifs that are shielded by interaction partners to facilitate ER exit (Zerangue et al, 1999; Michelsen et al, 2005). However, no functional arginine-based or other linear signal sequence could be identified in the N-terminus of CIC-4 that reportedly localizes it to the ER (Okkenhaug et al, 2006).

Although both CIC-3 and CIC-4 are widely expressed across tissues, their relative expression levels vary (Fig EV2B). Expression databases (<https://gtportal.org/>) suggest that both isoforms are expressed to roughly similar levels in brain and muscle, but that the CIC-3/CIC-4 mRNA ratio is markedly higher in most other tissues. Cells probably co-express heteromeric and homomeric CIC-3 and CIC-4 exchangers since CIC-3 does not require CIC-4 for ER exit, and because a fraction of CIC-4 can leave the ER without CIC-3. This is

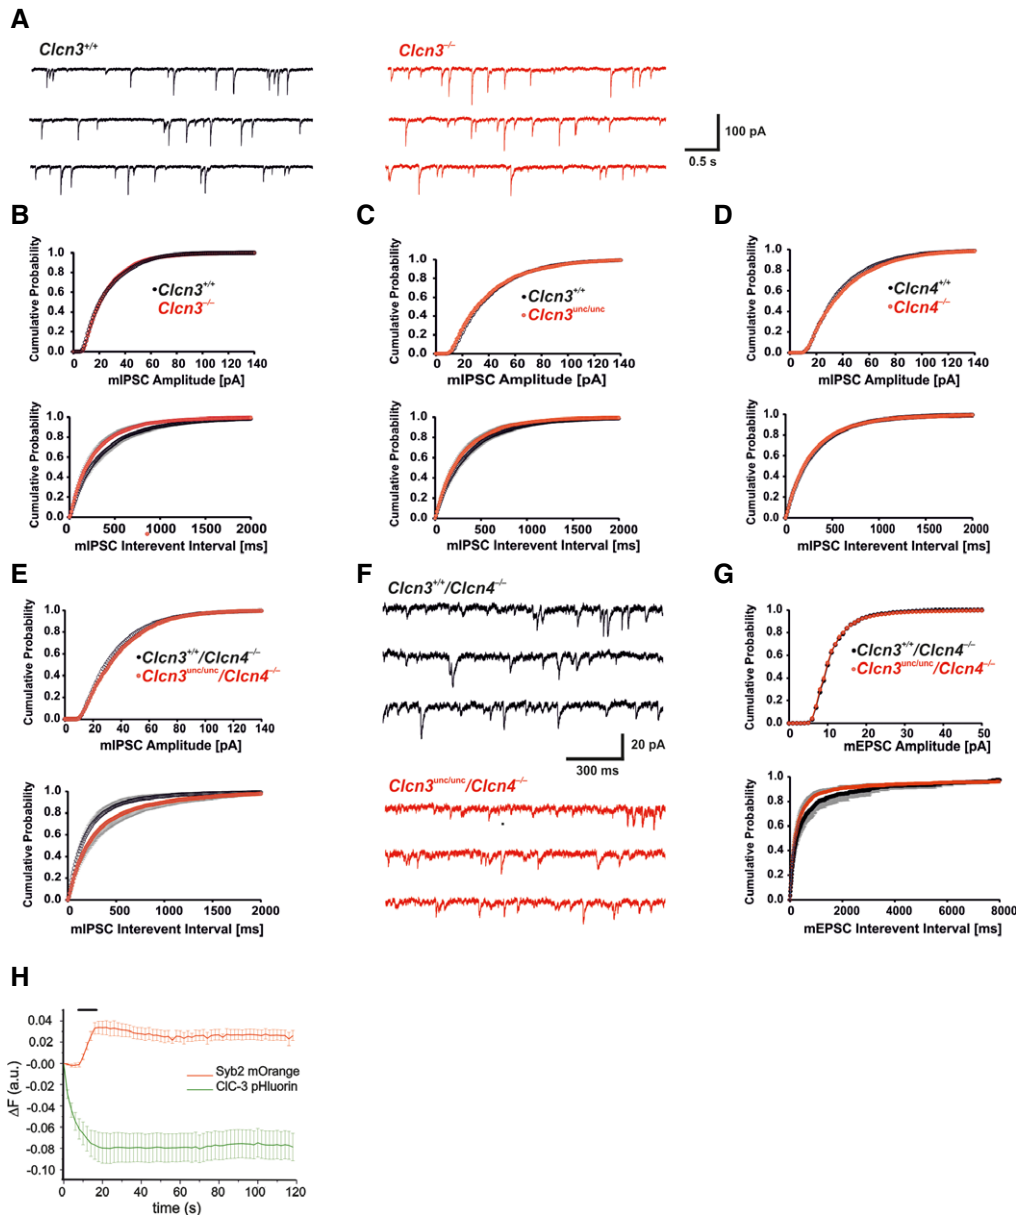

Figure 6. Impact of *Clcn3* and *Clcn4* genotypes on synaptic vesicle exocytosis.

A–E Miniature inhibitory postsynaptic currents (mIPSCs) measured in CA1 pyramidal neurons in different mouse models at P14–P16. (A) Example mIPSCs of WT (left) and *Clcn3*^{−/−} neurons. (B–E) Mean values ± SEM and cumulative histogram of amplitude (top) and frequency/interevent–interval (bottom) of mIPSCs in different mouse models as indicated. Several cells of three mice of each genotype were analyzed. Compared genotypes were siblings. No difference in amplitude or frequency/interevent–interval distribution of mIPSCs was found in (B) *Clcn3*^{−/−} and *Clcn3*^{+/+} (*Clcn3*^{+/+}: 16 cells, *Clcn3*^{−/−}: 15 cells; mean amplitude: $P > 0.8$, t -test; mean frequency: $P > 0.4$, MW test), in (C) *Clcn3*^{unc/unc} and *Clcn3*^{+/+} (*Clcn3*^{+/+}: 21 cells, *Clcn3*^{unc/unc}: 13 cells; mean amplitude: $P > 0.7$; mean frequency: $P = 0.3$, t -test), and in (D) *Clcn4*^{−/−} and *Clcn3*^{+/+} (*Clcn3*^{+/+}: 18 cells, *Clcn4*^{−/−}: 18 cells; mean amplitude: $P > 0.3$, t -test; mean frequency: $P = 0.6$, MW test). (E) No difference in mean amplitude ($P > 0.5$, t -test), in cumulative amplitude and mean frequency of mIPSCs ($P > 0.1$, t -test) was found in *Clcn3*^{unc/unc}/*Clcn4*^{−/−} and *Clcn3*^{+/+}/*Clcn4*^{−/−}. The interevent–interval distribution was shifted to the right, indicating a reduced frequency of mIPSCs in *Clcn3*^{unc/unc}/*Clcn4*^{−/−} (KS test, $P < 0.05$; *Clcn3*^{+/+}/*Clcn4*^{−/−}: 16 cells, *Clcn3*^{unc/unc}/*Clcn4*^{−/−}: 12 cells).

F, G Miniature excitatory postsynaptic currents (mEPSCs). (F) Example traces of mEPSCs in WT and *Clcn3*^{−/−} neurons. (G) No significant difference between *Clcn3*^{unc/unc}/*Clcn4*^{−/−} and *Clcn3*^{+/+}/*Clcn4*^{−/−} mEPSCs in mean amplitudes ($P > 0.9$, t -test) or in the distribution of amplitudes (*Clcn4*^{−/−}: 12 cells, 2 mice; *Clcn3*^{unc/unc}/*Clcn4*^{−/−}: eight cells, two mice).

H Primary hippocampal neurons co-transfected with CIC-3 and synaptobrevin (syb2), both luminally tagged with pHluorin or the pH-sensitive mOrange (Ramirez et al, 2012), respectively, were stimulated by 200 action potentials (APs) at 20 Hz (indicated by bar). Vesicle exocytosis was monitored by fluorescence increase upon exposure to extracellular neutral pH. Note that only Syb2 and not CIC-3 shows signs of exocytosis. Traces were corrected for photobleaching. The initial decay of the pHluorin signal is probably due to the high light exposure, which forces the fluorophores into a transient dark state (Dean et al, 2011). Averaged fluorescence traces ($n = 10$), error bars, SEM.

Source data are available online for this figure.

indicated by the mature CIC-4 band in Western blots of *Clcn3*^{-/-} tissue and by robust plasma membrane currents upon CIC-4 overexpression (Friedrich *et al*, 1999; Picollo & Pusch, 2005; Scheel *et al*, 2005).

Transport properties of CIC-3 and CIC-3/4 heteromers

Due to difficulties in obtaining sizeable plasma membrane currents with CIC-3, various endogenous and mutually exclusive currents were assigned to CIC-3 (Kawasaki *et al*, 1994, 1995; Duan *et al*, 1997; Huang *et al*, 2001). However, analysis of splice variants and mutants with increased surface expression have firmly established that CIC-3 generates strongly outwardly rectifying currents (Li *et al*, 2000; Picollo & Pusch, 2005; Matsuda *et al*, 2008; Guzman *et al*, 2013, 2015; Okada *et al*, 2014; Rohrbough *et al*, 2018) resembling those of the closely related CIC-4 and CIC-5 exchangers (Steinmeyer *et al*, 1995; Friedrich *et al*, 1999). Neutralizing the “gating glutamate” linearizes the current/voltage relationship of CIC-3 (Fig EV1B) (Matsuda *et al*, 2008; Okada *et al*, 2014; Rohrbough *et al*, 2018) and abolishes the coupling of Cl⁻ flux to H⁺-countertransport like in other vesicular CLCs (Friedrich *et al*, 1999; Picollo & Pusch, 2005; Scheel *et al*, 2005; Neagoe *et al*, 2010; Leisle *et al*, 2011), as convincingly shown for a chimera in which the CIC-3 N-terminus was replaced by CIC-5 (Rohrbough *et al*, 2018). The hypothesis that CIC-3 facilitates acidification of endosomes by increasing the capacitance of their membrane (Guzman *et al*, 2013) is not viable when luminal buffering of H⁺ is taken into account (Jentsch & Pusch, 2018).

We do not know whether the ion transport properties of CIC-3/4 heteromers differ in detail from a superposition of those from the respective homodimers. Currents elicited by co-expressing CIC-3 and CIC-4 are overwhelmingly mediated by CIC-4 because CIC-3 current amplitudes are very low. The Cl⁻/H⁺-exchange of CIC-4 is almost certainly maintained in a heterodimer with the uncoupled CIC-3^{unc} protein because ion translocation pathways of CLC proteins are entirely enclosed in each individual subunit (Ludewig *et al*, 1996; Weinreich & Jentsch, 2001; Dutzler *et al*, 2002). Protonation of the side chain of the “gating glutamate”, which protrudes into the permeation pathway, is thought to underlie gating of CLC channels and Cl⁻/H⁺-exchange of CLC exchangers like CIC-3 (Dutzler *et al*, 2002, 2003; Accardi & Miller, 2004). Hence not only ion selectivity and single channel conductance (Ludewig *et al*, 1996; Weinreich & Jentsch, 2001), but also other pore properties such as Cl⁻/H⁺-coupling are independent from the other subunit of the dimer, as demonstrated with concatemers linking WT and uncoupled CIC-5 subunits (Zdebik *et al*, 2008). The changed properties of CIC-1/CIC-2 (Lorenz *et al*, 1996) and CIC-0/CIC-1 (Weinreich & Jentsch, 2001) Cl⁻ channels or CIC-7/CIC-7^{mutant} chloride/proton exchangers (Ludwig *et al*, 2013) are caused by altered common gating that acts on both subunits (Ludwig *et al*, 2013). Since CIC-3 and CIC-4 currents display similar activation kinetics, no effect of heteromerization is expected.

CIC-3 localizes predominantly to endosomes rather than SVs

Although initially thought to be a plasma membrane Cl⁻ channel (Kawasaki *et al*, 1994, 1995; Duan *et al*, 1997; Huang *et al*, 2001), it is now established that CIC-3 is a Cl⁻/H⁺-exchanger that resides

almost exclusively on intracellular membranes. Upon overexpression in COS-7 cells, only ~6% of the protein was found at the plasma membrane where it was rapidly endocytosed and targeted to endosomes (Zhao *et al*, 2007). We expect native plasma membrane expression to be even much lower. In any case, CIC-3 is unlikely to be active at the plasma membrane because its currents are only observed at non-physiological cytoplasm-positive voltages.

Most groups now concur that CIC-3 is expressed on endosomes, but almost all studies relied on heterologous overexpression (e.g., Li *et al*, 2002; Hara-Chikuma *et al*, 2005b; Suzuki *et al*, 2006; Weylandt *et al*, 2007; Zhao *et al*, 2007). Anti-CIC-3 antibodies were often used without KO controls and can show significant cross-reactivity (Jentsch *et al*, 2010). Our own anti-CIC-3 antibody has been validated by using *Clcn3*^{-/-} tissue, but gives only faint signals in IHC. To unambiguously localize CIC-3 in native tissues, we newly generated *knock-in* mice expressing a Venus-CIC-3 fusion protein. *Clcn3*^{ven/ven} mice revealed that native CIC-3 is found on intracellular punctate structures, which mainly represent early, recycling and partially late endosomes.

Several groups, including our own (Stobrawa *et al*, 2001; Maritzen *et al*, 2008), have suggested the presence of CIC-3 on SVs (Salazar *et al*, 2004; Seong *et al*, 2005; Grønberg *et al*, 2010; Riazanski *et al*, 2011; Guzman *et al*, 2014) or synaptic-like microvesicles of neuroendocrine cells (Salazar *et al*, 2004; Maritzen *et al*, 2008). However, it was later reported that only every 2,000th SV may contain a CIC-3 molecule (Schenck *et al*, 2009). One proteomic study found CIC-3 on SVs (Grønberg *et al*, 2010), whereas three others did not (Takamori *et al*, 2006; Boyken *et al*, 2013; Biesemann *et al*, 2014), and reports concerning effects of CIC-3 disruption on SV function are contradictory (Stobrawa *et al*, 2001; Schenck *et al*, 2009; Riazanski *et al*, 2011; Guzman *et al*, 2014).

We therefore used multiple approaches to re-investigate a potential role of CIC-3 in SVs. Calibrated Western blots from SV-enriched LP2 fractions suggested the presence of one CIC-3 protein per ~25 SVs (4%) in mouse brain, considerably higher than 1 CIC-3 per 2,000 SVs as reported by Schenck *et al* (2009). These authors have overestimated VGLUT1 levels due to an inadvertent epitope shielding in their antibody calibration procedure that used C-terminally tagged VGLUT1 (S. Takamori, *personal communication*). Quantitative single-vesicle imaging of SVs from *Clcn3*^{ven/ven} mice yielded an even higher estimate (≥ 10% CIC-3 expressing SVs), whereas electrically stimulated exocytosis of SVs from CIC-3-phluorin transfected neurons failed to provide evidence for a significant presence of CIC-3 on SVs. Each of these techniques is fraught with potential pitfalls such as epitope shielding with epitope-tagged proteins, or effects of epitope addition or overexpression on the trafficking of CIC-3. With these caveats in mind, our experiments suggest that SVs do express CIC-3, with about 4–15% of SVs being positive. CIC-3-positive SVs may represent a functionally distinct subpopulation of SVs, such as endosomal intermediates in SV reformation after endocytosis. However, we did not observe an impact of the loss of CIC-3 on synaptic function before the onset of neurodegeneration and the concomitant loss of VGLUT1.

CIC-3 was proposed to support SV acidification by shunting H⁺-ATPase currents (Stobrawa *et al*, 2001). Indeed, acidification of SV preparations from *Clcn3*^{-/-} mice was reduced (Fig 5C) as reported before (Stobrawa *et al*, 2001; Riazanski *et al*, 2011). However, one previous study (Riazanski *et al*, 2011) based this conclusion in part

on a so-called “rat CIC-3 KO model” in which CIC-3-containing vesicles were immuno-depleted from SV preparations. Obviously, the CIC-3-depleted vesicle population is not equivalent to SVs from *Clcn3*^{-/-} mice. Our present work supports the suggestion of Takamori and colleagues (Schenck *et al*, 2009) that the reduced acidification of SVs from *Clcn3*^{-/-} mice (Stobrawa *et al*, 2001) can be attributed to a reduction of the vesicular glutamate transporter VGLUT1 which we had observed earlier (Stobrawa *et al*, 2001). VGLUT1 appears to operate in several modes which includes a Cl⁻ conductance (Schenck *et al*, 2009; Preobraschenski *et al*, 2014; Martineau *et al*, 2017). The fact that > 65% of purified SVs are glutamatergic (Takamori *et al*, 2006) is compatible with this hypothesis. The impairment of SV acidification correlated with a reduction of VGLUT1 levels during neurodegeneration in both *Clcn3*^{-/-} and *Clcn3*^{unc/unc}/*Clcn4*^{-/-} mice. Although CIC-3 and CIC-4 are expressed from birth on, no acidification defect was observed in *Clcn3*^{-/-} mice before the onset of neurodegeneration. Since the loss of VGLUT1 roughly correlated with the degree of neurodegeneration, it might be owed to a preferential loss of mainly glutamatergic hippocampal neurons or, less likely, from a trafficking defect of VGLUT1.

The previously proposed role of CIC-3 in SV acidification suggested that it might affect SV neurotransmitter uptake. Depending on the particular neurotransmitter transporter, this uptake is driven by ΔpH and/or the transmembrane voltage (Δψ). Glutamate uptake depends mainly on Δψ, whereas the activity of the vesicular GABA transporter VGAT depends on both parameters (Hnasko & Edwards, 2012). If CIC-3 provides a significant SV conductance, one would expect that *Clcn3* disruption increases Δψ and hence glutamate uptake. This should translate into larger miniature excitatory postsynaptic currents (mEPSCs) that are proportional to the vesicular glutamate content. Since disruption of a SV Cl⁻ conductance would not only increase Δψ, but also decrease ΔpH, an effect on GABA loading and mIPSCs is difficult to predict. In general, mPSCs must be interpreted cautiously because degenerative changes in *Clcn3*^{-/-} neurons may begin earlier than is apparent from light microscopy and since the lack of the overwhelmingly endosomal CIC-3 protein may affect intracellular trafficking of key proteins.

We previously measured mIPSCs and mEPSCs in CA1 pyramidal neurons of WT and *Clcn3*^{-/-} mice before the onset of neuronal cell loss (P13–P15) (Stobrawa *et al*, 2001). We found no differences of mIPSC amplitudes or frequencies and only a slight increase in mEPSCs that was apparent in the amplitude distribution, but not in their mean values (Stobrawa *et al*, 2001). In contrast, Riazanski *et al* (2011) more recently described significantly lower mIPSC amplitudes and a ~ 40% decrease in their frequency, and Guzman and colleagues reported a 20% increase in mean mEPSC amplitudes and an ~ 80% increase in mEPSC frequencies in hippocampal neurons cultured from WT and *Clcn3*^{-/-} mice (Guzman *et al*, 2014).

We re-investigated this issue and measured mIPSCs in hippocampal slices from 13- to 15-day-old mice. mIPSC amplitudes or frequencies were neither changed in *Clcn3*^{-/-}, nor in *Clcn3*^{unc/unc} or *Clcn4*^{-/-} mice. Only *Clcn3*^{unc/unc}/*Clcn4*^{-/-} mice, which show the strongest neurodegeneration, displayed reduced mIPSC frequencies. The effects reported by Riazanski *et al* (2011), who studied *Clcn3*^{-/-} mice (Dickerson *et al*, 2002) at P18–P25, might thus be due to incipient neurodegeneration. We examined mEPSCs in *Clcn3*^{unc/unc}/*Clcn4*^{-/-} mice and again found no differences in mEPSC amplitudes. In conclusion, our data neither support a significant presence of

CIC-3 on SVs, nor a degeneration-independent role in synaptic transmission. Our data do not support the influence of *Clcn3* disruption on SV size described by Guzman *et al* (2014) either.

Biological roles of CIC-3 and CIC-4

The strong reduction of CIC-4 in *Clcn3*^{-/-} mice likely contributes to their severe neurodegeneration although *Clcn4*^{-/-} mice lack obvious phenotypes (Rickheit *et al*, 2010; Hu *et al*, 2016). In humans, *CLCN4* mutations were identified in patients with mental retardation and sometimes seizures (Veeramah *et al*, 2013; Hu *et al*, 2016; Palmer *et al*, 2018), but no overt neurodegeneration was reported. Primary cultures of hippocampal neurons from *Clcn4*^{-/-} mice showed borderline reductions in dendritic branching (Hu *et al*, 2016), but no changes in brain morphology were observed here (Appendix Fig S2).

Our work suggests that the neurodegeneration of *Clcn3*^{-/-} mice is owed to a decrease of endosomal Cl⁻/H⁺ exchange below a critical threshold which is passed because loss of CIC-3 also entails a marked decrease of CIC-4. When endosomal Cl⁻/H⁺ exchange is further reduced (and possibly abolished, if no other CLCs are present in the relevant compartments) as in *Clcn3*^{unc/unc}/*Clcn4*^{-/-} or *Clcn3*^{-/-}/*Clcn4*^{-/-} mice, the ensuing pathology is even more pronounced (Fig 3A and B). Comparison of *Clcn3*^{unc/unc}/*Clcn4*^{-/-} with *Clcn3*^{-/-}/*Clcn4*^{-/-} mice suggests that the uncoupled CIC-3^{unc} Cl⁻ conductance might partially substitute for cellular functions of CIC-3 Cl⁻/H⁺ exchange. Alternatively or additionally, a lack of CIC-3 protein interactions, which will be retained with the CIC-3^{unc} mutant, might account for the more severe phenotype of *Clcn3*^{-/-}/*Clcn4*^{-/-} mice. Indeed, we previously found partial rescues of *Clcn7*^{-/-} phenotypes (Kornak *et al*, 2001; Kasper *et al*, 2005) both by the uncoupled conductance of CIC-7^{unc} in *Clcn7*^{unc/unc} mice (Weinert *et al*, 2010) and by the mere presence of the CIC-7 protein in *Clcn7*^{td/td} mice that express a transport-deficient mutant (Weinert *et al*, 2014).

As repeatedly shown for CIC-5 (Günther *et al*, 2003; Hara-Chikuma *et al*, 2005a; Novarino *et al*, 2010; Gorvin *et al*, 2013), endosomal/lysosomal CLCs may support vesicular acidification by neutralizing H⁺-ATPase currents. Steady-state pH (Yoshikawa *et al*, 2002) and active acidification (Hara-Chikuma *et al*, 2005b) of endosomes from *Clcn3*^{-/-} hepatocytes were reported to be more alkaline and reduced, respectively. As both CIC-3 and CIC-4 are expressed in liver, a reduction of CIC-4 may have contributed to this effect. A mild alkalization (pH 6.6 vs. 6.1) was reported for transferrin-positive compartments of *Clcn3*^{-/-} hepatocytes (Hara-Chikuma *et al*, 2005b), but we found no significant change in the pH of these compartments in cultured *Clcn3*^{-/-} neurons. Acidification of intracellular compartments does not always depend on Cl⁻. For instance, lysosomes lacking CIC-7 display normal steady-state pH (Kasper *et al*, 2005; Weinert *et al*, 2010, 2014) because their acidification depends largely on cation counterflux (Steinberg *et al*, 2010).

Given that Cl⁻/H⁺-exchange accumulates Cl⁻ in acidic vesicles in a secondary active process, we expect that luminal Cl⁻ concentrations in *Clcn3*^{-/-} and *Clcn3*^{unc/unc}/*Clcn4*^{-/-} endosomes are decreased. Lower Cl⁻ concentrations have been measured in lysosomes of cells derived from *Clcn7*^{-/-} and *Clcn7*^{unc/unc} mice (Weinert *et al*, 2010, 2014) and in *Caenorhabditis elegans* lysosomes lacking the CIC-7 ortholog (Chakraborty *et al*, 2017). Whereas lysosomes can be easily loaded with dextran-coupled indicators, we are

currently unable to specifically target Cl^- sensors to endosomes. CIC-3 may also influence the voltage across endosomal membranes. Model calculations predict more negative luminal voltages with $2\text{Cl}^-/\text{H}^+$ -exchangers than with Cl^- channels (Weinert et al, 2010), but no reliable methods to quantitatively measure endosomal voltage exist. In conclusion, disruption of CIC-3 may affect the luminal pH and Cl^- concentration and the transmembrane voltage of CIC-3-expressing vesicles. However, for $\text{Clcn3}^{\text{unc}/\text{unc}}/\text{Clcn4}^{-/-}$ mice, which display more severe pathology than $\text{Clcn3}^{-/-}$ mice, no change in luminal pH is expected because the $\text{Clcn3}^{\text{unc}} \text{Cl}^-$ conductance may support acidification as observed in $\text{Clcn3}^{\text{unc}}$ mice (Novarino et al, 2010).

Our work suggests that the severe neurodegeneration observed in $\text{Clcn3}^{-/-}$ mice or $\text{Clcn3}^{\text{unc}/\text{unc}}/\text{Clcn4}^{-/-}$ mice is due to an impairment of endosomal, rather than SV function. The loss of CIC-3, together with the concomitant substantial reduction of its heteromerization partner CIC-4, may alter intracellular trafficking as in other neurodegenerative diseases caused by mutations in endolysosomal ion transport proteins (LaPlante et al, 2006; Ouyang et al, 2013). The observation that the replacement of the Cl^-/H^+ -exchange activity of CIC-3 by a Cl^- conductance leads to severe pathology when not compensated by CIC-4 generalizes the emerging picture (Jentsch, 2007; Braun et al, 2010; Novarino et al, 2010; Weinert et al, 2010) that the function of endosomes and lysosomes depends on Cl^- accumulation or changes in membrane potential brought about by $\text{Clcn3} \text{Cl}^-/\text{H}^+$ exchangers.

Materials and Methods

Mice

The generation of $\text{Clcn3}^{-/-}$ and $\text{Clcn4}^{-/-}$ mice (Stobrawa et al, 2001) has been described. For the generation of $\text{Clcn3}^{\text{unc}/\text{unc}}$ mice 11.7 kb of mouse genomic sequence extending from exon 2 to 6 of *Clcn3* were amplified from R1 ES cells and cloned into pKO Scrambler plasmid 901 (Lexicon Genetics Incorporated) containing a dtA cassette (diphtheria toxin A cassette). A neomycin (neo) resistance cassette flanked by FRT sites was introduced between exon 5 and 6 to select for recombination in embryonic stem (ES) cells. Exon 5 was modified by insertion of the E224A mutation. Targeted R1 ES cells were screened by Southern blot (SB) analysis using EcoRV and an external 1.2-kb probe. Correctly targeted ES cells were injected into C57Bl/6 blastocysts. Chimeric animals were crossed with FLPe recombinase-expressing “deleter” mice (Farley et al, 2000) and resulting heterozygous animals ($\text{Clcn3}^{+/\text{unc}}$) were inbred to yield $\text{Clcn3}^{\text{unc}/\text{unc}}$. Exon 5 of the genomic *Clcn3*^{unc/unc} gene was amplified with intronic primers and sequenced. To obtain double genetically modified $\text{Clcn3}^{\text{unc}/\text{unc}}/\text{Clcn4}^{-/-}$ mice, heterozygous $\text{Clcn3}^{+/\text{unc}}/\text{Clcn4}^{+/-}$ mice were inbred.

To generate $\text{Clcn3}^{\text{ven}/\text{ven}}$ mice, 14.3 kb of mouse genomic sequence extending from exon 1 to 3 of *Clcn3* was subcloned into pKO Scrambler plasmid 901 (Lexicon Genetics) containing a dtA cassette from a murine *Clcn3* λ clone 7 isolated from a 129SVJ mouse genomic library cloned into pBlue. A puromycin (puro) resistance cassette flanked by loxP sites was introduced between exon 1 and 2 to select for recombination in ES cells. Venus cDNA was inserted by recombinant PCR onto the start ATG of the *Clcn3* ORF

which codes for the transcript variant a (NM_007711.3). Additionally, a silent point mutation was introduced to obtain an NcoI restriction site for subsequent SB analysis. The Venus and *Clcn3* sequences were separated by a 12-bp linker. Correctly targeted ES cells were injected into C57Bl/6 blastocysts. Chimeric animals were crossed with Cre-recombinase-expressing “deleter” mice (Schwenk et al, 1995), and resulting heterozygous animals ($\text{Clcn3}^{+/\text{ven}}$) were inbred to yield $\text{Clcn3}^{\text{ven}/\text{ven}}$. All experiments were performed with mice in a mixed C57Bl/6-129/Svj genetic background, always using littermates as controls. Animals were housed under standard conditions in the animal facility of the MDC according to institutional guidelines and kept on a 12-h light/dark cycle. LAGeSo, Berlin, Germany, approved all experimental procedures.

Antibodies

Primary antibodies were as follows: anti-CIC-3 and rabbit anti-CIC-4 (Maritzen et al, 2008), rabbit anti-CIC-5 (Günther et al, 1998), rabbit anti-synaptophysin (#101 002, Synaptic Systems), chicken anti-GFP (#1020 Aves lab), mouse anti-GFP (#A-11120, Life Technologies), rabbit anti-GFP (#A-11122, Life Technologies), rat anti-Lamp-1 (#553792, BD Pharmingen; clone 1D4B; BD Biosciences), mouse anti-Lamp-1 (clone H4A3, DHSB), rabbit anti-EEA1 (#PA1-063A, Thermo Scientific), mouse anti-EEA1 (#610457, Transduction Laboratories), mouse anti-TfR (#13-6890, Zymed), guinea pig anti-VGLUT1 (#135 304, Synaptic Systems), mouse anti-VGLUT1 (#135 311, Synaptic Systems), rabbit anti-VGLUT1 (#135 303, Synaptic Systems), guinea pig anti-VGLUT2 (#135 404, Synaptic Systems), mouse anti-VGAT (#131 011, Synaptic Systems), rabbit anti-clathrin heavy chain (ab21679, Abcam), rabbit anti-LC3 (#AP1802a, Abgent), rabbit anti-GluR4 (#06-308, Millipore), rabbit anti-GABA_A-receptor $\alpha 1$ (#06-868, Millipore), mouse anti-MAP2 (#MAB3418, Millipore), mouse anti-PSD95 (#MA1-046/CP35, Thermo Scientific/Calbiochem), mouse anti-GFAP (#G3893, Roche), mouse anti-APC (#OP80, Calbiochem), mouse anti-GM130 (#610823, BD Biosciences), mouse anti-rab4 (#610889, BD Biosciences), mouse anti-rab3 (#107 011, Synaptic Systems), mouse anti-adaptin Y (AP-1, #610385, BD Transduction) mouse anti-PDI (#SPA-891, StressGen), mouse anti-cathepsin D (#28-0002, Zymed), rabbit anti- β -actin (#A2066, Sigma-Aldrich), rabbit anti- α -tubulin (#ab15246, Abcam), rat anti-HA (3F10, #118676423001, Roche). Secondary antibodies were coupled to Alexa Fluor 488, 546, 633 (Invitrogen) or HRP (Jackson ImmunoResearch).

Biochemical methods

For membrane preparation, tissues were homogenized in PBS with protease inhibitors (Complete[®], Roche) and cleared two times by centrifugation at 1,000 g for 10 min. Membranes were pelleted at 270,000 g for 30 min and subsequently resuspended in PBS supplemented with protease inhibitors and 2% (w/v) SDS. For whole tissue homogenates, organs were homogenized in PBS with 1% (v/v) NP-40 and protease inhibitors (Complete[®], Roche) and incubated for 30 min on ice. After centrifugation for 10 min at 20,800 g, the supernatant was used for SDS-PAGE. Equal amounts of protein were separated by SDS-PAGE and blotted onto nitrocellulose.

For deglycosylation, 60 μg of lysate was denatured at 65°C for 5 min in 0.5% (w/v) SDS for PNGase F (Roche) or in 0.5%

SDS, 40 mM DTT and 50 mM Na-acetate pH 5.2 for EndoH (Roche) treatment. After adjusting to 1% (v/v) NP-40 and 1.3 mM EDTA, 1 unit of PNGase F and 0.015 units of EndoH were added and samples incubated at 37°C for 2 h. For immunoprecipitation experiments, CIC-3 and CIC-4 antibodies were bound to protein A sepharose (GE Healthcare). Brain membranes were pelleted and solubilized in homogenization buffer (150 mM NaCl, 25 mM MES pH 6.5) containing 1% Triton X-100. Non-solubilized material was removed by a 20,360 g spin. After incubation with the protein A sepharose-antibody complexes for 12 h at 4°C and washing, samples were eluted in 2× SDS sample buffer at 75°C.

Quantification of CIC-3/VGLUT1 ratio in LP2 fraction

To estimate CIC-3 copy number relative to VGLUT1, we transiently expressed mVGLUT1 and hCIC-3 in HEK cells, both of which were N-terminally tagged with EGFP. The cells were lysed in equal volumes of 1× PBS containing 1% Triton X-100 and protease inhibitors (Complete[®], Roche), and soluble supernatant was used as standard for calibrating VGLUT1 and CIC-3 antibodies. Probing with GFP allowed us to directly compare the relative amounts of VGLUT1 and CIC-3 in the lysates. On average, we found that the GFP-hCIC-3 lysate contained about $4.33 \times$ more CIC-3 molecules than the GFP-VGLUT1 lysate contains VGLUT1 molecules. We then compared the two standards with different amounts of LP2 fractions (see below for LP2 preparation) from mouse brain by using our KO-controlled CIC-3 antibody and a VGLUT1 antibody directed opposite the GFP tag against the very C-terminus of VGLUT1 (see above). While the standard for VGLUT1 roughly corresponds to 2.5 µg of that LP2 fraction, the signal of the standard for CIC-3 corresponds to ~140 µg. Therefore, the amount of VGLUT1 and CIC-3 standards compared to LP2 fraction differs by a factor of 56. Given that the standard for CIC-3 contains 4.33 times more CIC-3-molecules than the standard for VGLUT1, the actual copy number of CIC-3 in the LP2 fraction is about 13 times lower.

Fluorescence resonance energy transfer (FRET) microscopy

COS-7 cells were transfected as described above. Imaging was performed in physiological solution (in mM: 115 NaCl, 3 KCl, 1 MgSO₄, 1 MgCl₂, 1 CaCl₂, 20 HEPES, 10 glucose, pH 7.4), using a LSM 510 META microscope (Carl Zeiss) equipped with a 40× oil-immersion objective (numerical aperture = 1.3), an argon laser ($\lambda = 514$ nm), and an infrared laser ($\lambda = 810$ nm, two photon). Donor (ECFP) emission spectra were recorded at 810 nm (two photon) excitation before and after acceptor photobleaching (EYFP, 514 nm laser).

Förster resonance energy transfer efficiencies were calculated from the donor emission at $\lambda = 436 - 500$ nm before and after photobleaching, using the following equation:

$$E = 1 - \frac{I_0}{I_{pb}}$$

E: energy transfer efficiency; *I*₀ = donor intensity before acceptor photobleaching; *I*_{pb} = donor intensity after acceptor photobleaching.

LP2 preparations and SV fraction acidification

Crude SVs (LP2) were purified as described (Huttner *et al*, 1983; Takamori *et al*, 2000). LP2 were resuspended in homogenization buffer [320 mM sucrose, 4 mM HEPES-KOH (pH 7.4)]. Acidification was measured with 100 µg LP2 by acridine orange quenching in 0.8 ml of assay buffer (115 mM sucrose, 60 mM KCl, 4 mM K₂SO₄, 200 µM acridine orange, 1.2 mM K-ATP, 10 mM MOPS, pH 7.3) in a Safas fluorometer (excitation, 492 nm, emission, 520 nm) at 32°C. The addition of 5 mM MgCl₂ after 60 s started the reaction. FCCP (10 µM) addition after 4 min dissipated the H⁺-gradient and terminated the reaction. Traces were normalized to the fluorescence at *t* = 60 s.

Single-vesicle imaging of venus-tagged SVs

Synaptic vesicles were purified from the brain of adult *Cln3^{ven/ven}* mice and immobilized on poly-L-lysine coated glass cover slips as previously described (Farsi *et al*, 2016). To perform IF imaging, primary labeled antibodies against VGLUT1 (Oyster-650 labeled, Cat. #135 303C5, Synaptic Systems) or synaptophysin (Oyster-650 labeled, Cat. #101 011C5, Synaptic Systems) were used. Prior to IF, immobilized SVs were fixed using 4% paraformaldehyde and blocked by 30-min incubation with phosphate-buffered saline (PBS) containing 5% bovine serum albumin (BSA). Imaging of SVs was performed using a Nikon Eclipse Ti-inverted microscope equipped with iLAS2 TIRF (Visitron Systems) and an EM-CCD camera (iXon+ DU-897E-BV; Andor Technology). Excitation was performed at 488 nm (for Venus imaging) and 640 nm (for IF imaging), and emission of SVs was collected through a quadband (405/488/561/647 nm, Chroma 89902) emission filter.

Histology and electron microscopy

Deeply anesthetized mice were perfused with 4% (w/v) PFA in PBS, and isolated tissues were postfixed overnight at 4°C. Three-micrometer paraffin sections of retina were used for H&E and Nissl staining, 8-µm paraffin sections of the brain for Nissl staining, and 8-µm cryosections for IHC. For IHC, sections were postfixed with 4% (w/v) PFA, permeabilized using 0.2% (v/v) Triton X-100 in PBS and blocked with 3% (w/v) BSA in PBS. Antibody incubation was in blocking buffer overnight at 4°C. For some CIC-3 labeling experiments, an antigen retrieval step (10 min in sodium citrate buffer, pH 6.0, at 95°C) was included after fixation.

For DAB peroxidase staining on paraffin sections, HRP-conjugated secondary antibodies were used (DAKO Envision+ HRP system). The peroxidase reaction was started using 500 mg/ml diaminobenzidine, 10 mM imidazole, 0.3% ammonium nickel sulfate, 0.003% H₂O₂ in 50 mM Tris; pH 7.6. Sections were washed and mounted in Kaiser's glycerol gelatine (Merck). Sections were then examined with a Zeiss Axiophot.

For electron microscopy, mice were perfused with 4% (w/v) PFA and 2.5% (v/v) glutaraldehyde in 0.1 M phosphate buffer (pH 7.4). Brains were cut in 200-µm sections with a vibratome, postfixed in 1% osmium tetroxide and 1.5% potassium hexacyanoferrat, and embedded in epoxy resin. Layer 4–5 of secondary visual cortex just above hippocampus was trimmed

and ultrathin sectioned. Glutamatergic synapses were identified by presence of their prominent postsynaptic densities and spine heads. Images were done using Zeiss EM 900 microscope and Morada G2 camera. Four pairs of wild-type and *Clcn3*^{-/-} animals were acquired with 20–25 boutons per animals analyzed for vesicle number. Vesicle sizes were analyzed in more than 700 vesicles per genotype.

Clcn3^{ven/ven} and wild-type mice were perfused with 4% PFA and 0.1% glutaraldehyde, postfixed overnight at 4°C. CA3 areas of hippocampi were dissected and formed into 1-mm³ blocks that have been cryoprotected in 2.1 M sucrose solution overnight and frozen in liquid propane on pins. Modified Tokuyasu sectioning was performed as described elsewhere. Sections were blocked with 10% BSA and stained with Invitrogen mouse anti-GFP antibodies (1:50) and secondary 10 nm gold coupled goat-anti-mouse antibodies (1:50; Dianova). Sections were embedded and contrasted using a mix of polyvinyl alcohol/sodium silicotungstate/sodium orthovanadate.

Golgi-Cox staining

Animals were sacrificed by cervical dislocation; brains were dissected, processed, and stained using FD Rapid Golgi Stain Kit according to the manufacturer's instructions. 100- μ m sections were cut, stained, and examined using a Zeiss Axiophot. *Clcn4*^{+/+} and *Clcn4*^{-/-} 8-week-old male littermates and 24-week-old female littermates were analyzed.

Expression constructs

For cell culture expression, human ClC-3 (transcript variant a, NM_001243372.1, but N-terminally lacking 58 amino acids) was cloned into pCIneo (Promega) and an HA epitope was inserted between amino acids Gly₄₀₆ and Ala₄₀₇ of hClC-4 (Friedrich *et al*, 1999) (extracytosolic loop) by PCR mutagenesis. The point mutation to generate hClC-3^{unc} (E224A) was introduced by PCR with primers carrying the mutation. For whole-cell patch-clamp studies, human ClC-3 (see above) was cloned into pEGFP-C1 (Clontech) with the linker sequence SGLRSRE. The point mutations 4xLA (in which all four leucines of the N-terminal dileucine cluster were mutated to alanine) were introduced by PCR with primers carrying the mutations. All constructs were confirmed by sequencing the complete ORF.

For pHluorin experiments in hippocampal neurons, pHluorin was inserted by recombinant PCR into pCIneo-hClC-3 between membrane helices L and M with linker sequences GA and TG N- and C-terminally, respectively.

For FRET experiments, human ClC-3 and ClC-4 (see above) were cloned into pEGFP-C1 and pEYFP-C1 (Clontech). The linker sequences were SGLRSREL and SGLRSRAQASNSVET for ClC-3 and ClC-4, respectively.

For antibody calibration, VGLUT1 (NP_892038.2) was amplified from mouse cDNA and cloned into pEGFP-C3 (Clontech). All constructs mentioned above were confirmed by sequencing the complete ORF.

Expression in cell culture and fluorescence microscopy

Plasmid DNA was transfected into cells using the PEI method (Brisault *et al*, 2003) or FuGENE6 (Roche Applied Science) according to

the manufacturer's instruction. Cells were grown for further 24–48 h before fixation with 4% paraformaldehyde in PBS for 10 min. For immunostaining, cells were incubated with 30 mM glycine in PBS for 5 min and permeabilized with 0.1% saponin in PBS for 10 min. Both primary and AlexaFluor-coupled secondary (Molecular Probes) antibodies were applied in PBS, 0.05% saponin supplemented with 3% BSA. Images were acquired with an LSM510 laser scanning confocal microscope equipped with a 63 \times 1.4 NA oil-immersion lens (Zeiss).

Primary cell culture and transfection

Hippocampi were dissected from P0 to P2 mice, dissociated with papain (20 units/ml) at 37°C for 30 min, and triturated by pipetting. Hippocampal neurons were placed on life cell dishes or six-well chamber slides coated with poly-D-lysine at a cell density of 1×10^5 cells/dish. For neuronal cycling experiments, neurons were transfected at 9–10 days *in vitro* (DIV) with the respective plasmid DNA using the Calcium Phosphate Transfection Kit (Promega Inc.).

Primary cortical astrocyte cultures were prepared from P0 to P2 mouse pups of mixed sex. After dissection and removal of meninges and blood vessels, cortices were sliced and incubated with trypsin-EDTA (0.05%) for 30–40 min at 37°C. Tissue was triturated and suspended in DMEM (PAN Biotech) supplemented with 10% fetal bovine serum (Invitrogen) and 1 \times penicillin/streptomycin (Invitrogen). Cells were plated at a density of 1×10^7 cells in a 75-cm² flask and maintained in a 5% CO₂ incubator at 37°C. The growth medium was exchanged with fresh medium twice a week. At 7DIV or when cells becoming ~90% confluent, cell culture container was vortexed at full speed just prior to cell dissociation for further propagation of astrocytes without contaminating oligodendrocytes.

Immunofluorescence of primary neurons and glial cells

On DIV14–18, primary neurons or glial cells were fixed with 4% PFA/PBS for 10 min at room temperature. Fixed cells were washed, incubated with 30 mM glycine in PBS for 5 min, and permeabilized with 0.1% saponin in PBS for 10 min. Both primary and AlexaFluor-coupled secondary (Molecular Probes) antibodies were applied in PBS, 0.05% saponin supplemented with 3% BSA. Cells were washed again and mounted in ImmunMount (Thermo Scientific).

Electrically stimulated SV exo- and endocytosis by pHluorin imaging

Live imaging of primary hippocampal neurons was performed using a sCMOS camera (Neo, Andor) on an inverted microscope (Eclipse Ti, Nikon) with a 40 \times oil-immersion objective and a 200-Watt mercury lamp (Lumen 200, Prior) under the control of μ Manager (Edelstein *et al*, 2010). Images were acquired every 2 s with 300 ms excitation using a filter set for pHluorin or mOrange (F36-526/F26-518, AHF Analysentechnik). Measurements were conducted at room temperature in physiological buffer [in mM: 170 NaCl, 3.5 KCl, 0.4 KH₂PO₄, 20 TES (2-[(2-hydroxy-1,1 bis(hydroxylmethyl)ethyl)amino]ethanesulfonic acid), 5 NaHCO₃, 5 glucose, 1.2 Na₂SO₄, 1.2 MgCl₂, 1.3 CaCl₂ (pH 7.4)]. Osmolarity was adjusted with mannitol to the osmolarity of the growth medium. Ten micromolar CNQX (6-cyano-7-nitroquinoxaline-2,3-dione, Sigma-Aldrich)

and 50 μM APV (2-amino-5-phosphonovaleuranic acid, Sigma-Aldrich) were added as specific AMPA and NMDA receptor antagonists, respectively. Neurons were stimulated by electric field stimulation with 200 action potentials (at 20 Hz, 100 mA) in a stimulation chamber (RC-47FSLP, Warner Instruments), and stimulation-induced pHluorin and mOrange responses were recorded. Only boutons showing mOrange responses upon electrical stimulation and pHluorin unquenching upon addition of basic buffer (physiological buffer with 50 mM NaCl replaced by NH_4Cl) were used for analysis.

Unquenching of mOrange causes a much weaker fluorescence increase than unquenching of pHluorin (mOrange2: 3.5-fold, super-ecliptic pHluorin: 50-fold) (Lin & Schnitzer, 2016). We intentionally fused the stronger pH sensor to ClC-3, in order to be able to see also weak signs of exocytosis. We used strong illumination schemes and therefore had to correct for photobleaching by fitting a monoexponential decay function (equation 1) to the signal. Bleach rates were calculated from the lifetime of mOrange decay (equation 2). Bleach rates were used to correct for bleaching of synaptic mOrange intensity traces (equation 3).

$$\text{Exponential Decay: } I(t) = bg + a \cdot e^{-t/\tau} \quad (1)$$

$I(t)$: intensity at time t ; bg : background signal; a : intensity at time 0; τ : lifetime.

$$\text{Bleach rate: } \lambda = e^{-1/\tau} \quad (2)$$

λ : bleach rate; τ : lifetime.

$$\text{Bleach Correction: } I_{bc}(t) = I(t) + \sum_{i=0}^t (1 - \lambda) \cdot (I(i) - bg) \quad (3)$$

$I_{bc}(t)$: bleach corrected intensity at time t ; $I(t)$: intensity at time t ; λ : bleach rate; bg : background.

Measurement of endosomal pH

Endosomal pH was measured by ratiometric fluorescence imaging of the pH-sensitive fluorescein-conjugated transferrin and the pH-stable Alexa546-conjugated transferrin. Primary hippocampal neurons were plated onto live cell dishes. When older than DIV14, they were incubated with 200 $\mu\text{g/ml}$ FITC-Tfn and 100 $\mu\text{g/ml}$ Alexa546-Tfn at 37°C for 20 min in growth medium. FITC-Tfn acts as a pH sensor, whereas the Alexa546-Tfn acts as an internal standard for uptake. Cells were washed twice with imaging solution (in mM: 140 NaCl, 2.5 KCl, 1.8 CaCl_2 , 1 MgCl_2 , 20 HEPES) supplemented with 1% BSA and 20 mM glucose) and imaged using a Zeiss LSM510 confocal laser scanning microscope under 40×1.4 NA oil-immersion lens. Using ImageJ regions of interest (ROI) were defined as areas above a fixed fluorescence threshold. Endosomal pH was calculated from the ratio of fluorescence intensity (Alexa546/FITC). At the end of each experiment, *in situ* calibration curves were obtained in isotonic K^+ -based solution (125 mM KCl, 25 mM NaCl, 20 mM HEPES for pH 7.4, 5.4, and MES for pH 4.4) supplemented with 10 μM of both nigericin and monensin (both Sigma-Aldrich). Cells were equilibrated for at least 2 min for each pH value. The resulting fluorescence intensity ratio as a function of pH was fit to a sigmoid and used to interpolate pH values from the experimental ratio data.

Hippocampal slice recordings

Horizontal hippocampal slices (300 μm) were prepared from juvenile mice (P14–P16) using standard methods. Recordings of CA1 pyramidal neurons were conducted at 34°C. Extracellular solution was artificial cerebrospinal fluid (ACSF) containing (in mM): NaCl 131, NaHCO_3 29, glucose 11, KCl 2.8, CaCl_2 2.5, MgSO_4 1.3, NaH_2PO_4 1.1, osmolarity 320 mosml/l, saturated with 95% O_2 /5% CO_2 (pH 7.4). Patch pipettes (2.5–4 M Ω) were filled with (in mM): CsCl 130, HEPES 10, MgATP 2, MgCl_2 2, EGTA 0.2, osmolarity 280–290 mosml/l, pH 7.3. Cells were held at -70 mV and miniature IPSCs were isolated by bath application of 1 μM TTX, 10 μM NBQX, and 50 μM D-AP5. Miniature EPSCs were isolated by 20 μM bicuculline and 1 μM TTX. The low frequency of spontaneous mEPSCs ($\sim 1/\text{min}$) was increased by adding 200 mM sucrose to the bath. The currents were recorded after an equilibration time of 2 min, low-pass-filtered at 2 kHz, sampled at 8 kHz, and visualized by pClamp 10.2 (Molecular Devices, Sunnyvale). Recordings were only used as long as regularly applied voltage pulses revealed stable series resistance. pClamp 10.2 and Mini Analysis Program (Synaptosoft, Decatur) were used for data analyses.

Patch-clamp measurements of transfected cells

Whole-cell patch-clamp experiments on HeLa cells used patch pipettes of 3–5 M Ω resistance filled with (in mM) 110 CsCl, 10 NaCl, 0.5 CaCl_2 , 1 EGTA, 2 MgATP, 40 HEPES, pH 7.4. The bath solution contained (in mM) 130 NaCl, 5 KCl, 1 MgCl_2 , 1 CaCl_2 , 10 glucose, 20 HEPES, pH 7.4. Osmolarity was adjusted with sucrose to 280–290 mOsmol/l for the pipette solution and to 300–310 mOsmol/l for the extracellular solution. Cells were held at -30 mV upon reaching the whole-cell configuration and currents were elicited using 1-s pulses ranging from -80 mV to $+140$ mV. Data were acquired with an EPC-10 double amplifier using Pulse software (HEKA).

Data analysis

Values are presented as mean \pm SEM (standard error of the mean). Statistical difference between means was assessed by the two-tailed *t*-test for two groups using the GraphPad Prism software. Specific details are given in the respective figure legends. To evaluate the statistical difference of the miniature inhibitory postsynaptic currents, mean amplitudes and frequencies were first assessed for the presence of a normal distribution using the Shapiro–Wilk test followed by the two-tailed *t*-test for two groups. If the values were not normally distributed, the Mann–Whitney test was applied. The statistical difference between the cumulative amplitudes and cumulative interevent intervals was assessed by the Kolmogorov–Smirnov test. Statistically significant values are indicated by * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$.

Acknowledgements

We thank T. Stauber and T. Breiderhoff for cloning expression constructs; K. Rabel, S. Hohensee, and C. Backhaus for technical assistance; R. Jahn (MPIIbpc, Gottingen) for providing the equipment required for SV purification; and A.

Woehler (MDC, Berlin) for assistance with SV imaging. Supported, in part, by grants from the Deutsche Forschungsgemeinschaft (JE164/9-2, SFB740 TP C5, FOR 2625 (JE164/14-1), NeuroCure Cluster of Excellence), the European Research Council Advanced Grant CYTOVOLION (ERC 294435) and the Prix Louis-Jeantet de Médecine to TJJ, and Peter and Traudl Engelhorn fellowship to ZF.

Author contributions

TJJ and SW designed the project and wrote the manuscript. SW generated the *Clcn3^{unc}* and *Clcn3^{ven}* mouse models. SW, NG, DD, TS, DP, ZF, CFL, GN, KILC, and RPC performed experiments and analyzed data together with TJJ.

Conflict of interest

The authors declare that they have no conflict of interest.
