Abstract

Objective

In multiplex MS families, we determined the humoral immune response to Epstein-Barr virus nuclear antigen 1 (EBNA-1)-specific immunoglobulin γ (IgG) titers in patients with MS, their healthy siblings, and biologically unrelated healthy spouses and investigated the role of specific genetic loci on the antiviral IgG titers.

Methods

IgG levels against EBNA-1 and varicella zoster virus (VZV) as control were measured. *HLA-DRB1*1501* and *HLA-A*02* tagging single-nucleotide polymorphisms (SNPs) were genotyped. We assessed the associations between these SNPs and antiviral IgG titers.

Results

OR for abundant EBNA-1 IgG was the highest in patients with MS and intermediate in their siblings compared with spouses. We confirmed that *HLA-DRB1*1501* is associated with abundant EBNA-1 IgG. After stratification for *HLA-DRB1*1501*, the EBNA-1 IgG gradient was still significant in patients with MS and young siblings compared with spouses. *HLA-A*02* was not explanatory for EBNA-1 IgG titer gradient. No associations for VZV IgG were found.

Conclusions

In families with MS, the EBNA-1 IgG gradient being the highest in patients with MS, intermediate in their siblings, and lowest in biologically unrelated spouses indicates a genetic contribution to EBNA-1 IgG levels that is only partially explained by *HLA-DRB1*1501* carriership.

Glossary

EBNA-1 = EBV nuclear antigen 1; EBV = Epstein-Barr virus; IgG = immunoglobulin; SNP = single-nucleotide polymorphism; VCA = virus capsid antigen; VZV = varicella zoster virus.

Familial clustering in multiple sclerosis (MS) is supportive for strong genetic determinants in MS etiology. The *HLA-DRB1*1501*-containing haplotype is the strongest genetic MS-associated genetic risk factor, whereas *HLA-A*02* has a protective effect on MS.^{1,2} In addition, more than 200 non-HLA MS susceptibility loci with modest ORs have been identified.³ The associated genetic factors are seen more often in familial MS than in nonfamilial MS.^{4,5}

Besides genetic factors, environmental factors contribute to the risk of developing MS.⁶ A recent meta-analysis of twin studies showed that environmental influences contribute for 21% of MS liability variance.⁷ The major environmental risk factor is an infection with the Herpesviridae family member Epstein-Barr virus (EBV).^{8,9} Furthermore, immunoglobulin γ (IgG) response to EBV nuclear antigen 1 (EBNA-1) is heritable for 22%–43%, suggesting that host genetic factors are important in the immune response to EBV.^{10–12} In relation to EBV antibody titers in patients with MS and their twins and siblings, only a few small-sized studies were conducted that showed somewhat variable results.^{13–17}

The aim of our study was to determine the influence of genetic factors on humoral immune response toward EBNA-1 in multiplex families with MS, siblings, and controls. We hypothesized that because of shared genetic pool of patients with MS, their healthy siblings might have an increased IgG response to EBNA-1 compared with unrelated controls. Therefore, we determined serum EBNA-1 and varicella zoster virus (VZV) IgG as a control herpesvirus not associated with the development of MS¹⁸ in these 3 groups and assessed the influence of *HLA-DRB1*1501* and *HLA-A*02* on antiviral titers.

Methods

Study participants

Most participants (257 patients with MS and 173 unaffected siblings from 136 multiplex families with MS and their 135 unrelated healthy spouses) were included from the still ongoing study on gene-environment interaction in MS in the Netherlands. In this study, multiplex families with MS are included, in which at least one first- or second-degree relative of an affected proband was also diagnosed with MS. The remaining participants (44 patients with MS, 25 unaffected siblings, and 39 healthy spouses) were included from the Genetic Research in Isolated Populations study. Details of ascertainment are described elsewhere.¹⁹ The diagnosis of MS in all patients was evaluated according to the standard diagnostic criteria.^{20,21}

Serologic testing

Sera samples were collected and stored at -80°C . Serum EBNA-1 IgG and VZV IgG levels were determined using well-validated chemiluminescent assays (Liaison XL, DiaSorin) according to the manufacturers' instruction. In samples negative for EBNA-1, antiviral capsid antigen (VCA) IgG (DiaSorin) was measured to ascertain EBV seroprevalence. If antibody levels were above the threshold of the assay, the samples were diluted 20-fold using sample diluent (DiaSorin) and reanalyzed. EBNA-1 and VCA double seronegative and VZV seronegative individuals were omitted from further analyses to prevent bias.

Genotyping

Genomic DNA was isolated using standardized methods.²² MS-associated single-nucleotide polymorphisms (SNPs; table e-1, links.lww.com/NXI/A297) were genotyped using the Sequenom platform according to manufacturers' instruction. The average genotype call rate for both SNPs was 99%.

Statistical analysis

Data were analyzed using SPSS version 25.0 (SPSS Inc), and GraphPad Prism5 (GraphPad) was used to construct the graphs. Cases with missing data were omitted. EBNA-1 and VZV IgG titers were not normally distributed, also not after log transformation (both $p < 0.001$, Kolmogorov-Smirnov test). Therefore, IgG levels were dichotomized as above or below the 75th percentile of the levels of the spouses. We used 2-tailed *t*-test or nonparametric Mann-Whitney *U* test to compare continuous variables. Chi-square test or Fisher exact test were used to analyze nominal data. Generalized linear models (GLM) were used for the pairwise comparison of the study groups in relation to EBNA-1 and VZV titers, adjusted for gender, and household (i.e., to which family the samples belong to). Dichotomized IgG levels were also used to assess the ORs (OR) for the MS risk SNPs. ORs and associated CIs were calculated using logistic regression. The number of homozygous SNP carriers for a minor allele in both SNPs was <50 ; therefore, the homozygous group was pooled with heterozygous allele carriers (table e-2, links.lww.com/NXI/A297) to improve power. Two-sided *p*-values less than 0.05 were considered significant. Significance is indicated in the figures as $*p < 0.05$, $**p < 0.01$, $***p < 0.001$. Bonferroni correction was applied to correct for multiple testing.

Standard protocol approvals, registrations, and patient consents

Written informed consent was obtained from all participants with approval from the medical ethical committee of the Erasmus MC (Rotterdam, the Netherlands).

Data availability

All data are available from the corresponding author.

Results

This study included a total of 301 patients with MS, their 198 unaffected siblings, and 174 unrelated healthy spouse controls (see figure 1 for the study flowchart). Table 1 shows the clinical and demographic characteristics of the study population.

EBNA-1 IgG titers were inversely correlated with age

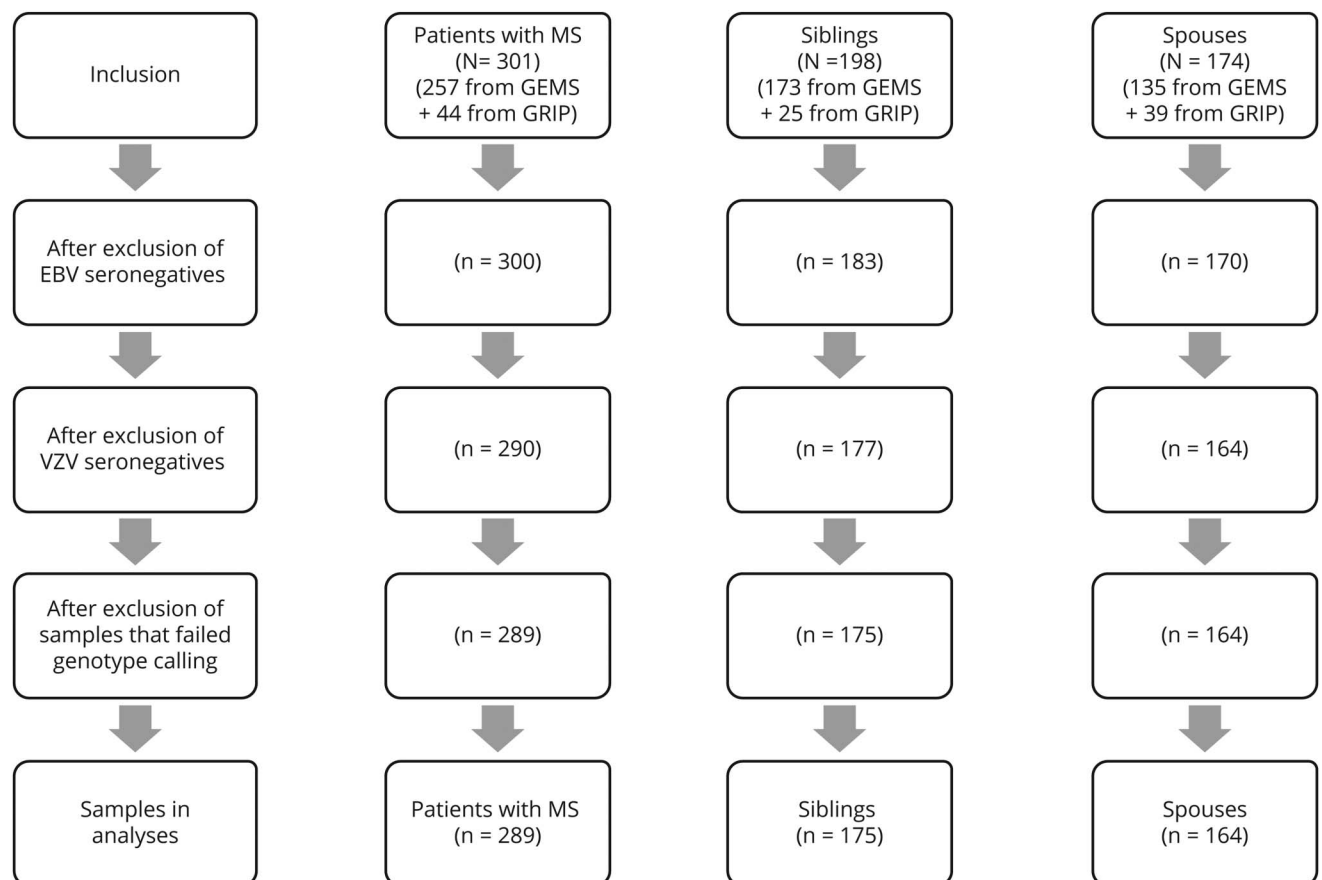

EBV seroprevalence in patients with MS was higher than in their spouses and their siblings (table 1). No differences were found in VZV seroprevalence between all study groups. A one-way analysis of variance showed that the effect of age at sampling was significant ($F(2,662) = 11.3, p = 1.5 \times 10^{-5}$). Patients with MS were significantly younger than siblings and spouses (table 1). Age was inversely correlated with EBNA-1 IgG titers (Spearman's $\rho = -0.1, p = 1.3 \times 10^{-2}$), and age at sampling was lower in the group with high EBNA-1 titers (>75th percentile) (mean age 48.3 years, 95% CI 46.8–49.8) compared with the group with low EBNA-1 IgG

titers (<75th percentile) (mean age at sampling 50.6 years, 95% CI 49.4–51.9, adjusted $p = 2.0 \times 10^{-2}$). Therefore, we stratified all data into 2 age groups by using the median age, i.e., younger than 50 (young, <50 years) and older than 50 years of age at sampling (old, >50 years). Young patients with MS had higher EBNA-1 IgG titers compared with elderly patients with MS (OR = 1.7, 95% CI 1.0–2.7, adjusted $p = 3.5 \times 10^{-2}$).

EBNA-1 IgG titers were highest in patients with MS, intermediate in siblings, and lowest in their spouses

Young patients with MS (<50 years) had an increased risk for high EBNA-1 IgG titers (>75th percentile) compared with spouses (figure 2A). In addition, young siblings had an increased risk for high EBNA-1 IgG titers compared with spouses (figure 2A). In this age group, patients with MS were more likely to have high EBNA-1 IgG titers compared with siblings (OR = 2.7, 95% CI 1.5–5.0, adjusted $p = 2.0 \times 10^{-3}$). In addition, elderly patients with MS (>50 years) had an increased risk for high EBNA-1 titers

Figure 1 Flowchart of the study

Only genotyped EBV (determined as EBV nuclear antigen 1 or viral capsid antigen IgG positive individuals) and VZV IgG-seropositive individuals were included in this study. EBV = Epstein-Barr virus; GEMS = study on gene-environment interaction in MS; GRIP = genetic research in isolated populations program; IgG = immunoglobulin; VZV = varicella zoster virus.

Table 1 Clinical and demographic characteristics of patients with MS, siblings, and spouses

Abbreviations: CIS = clinically isolated syndrome; EBV = Epstein-Barr virus; EDSS = Expanded Disability Status Scale; MSSS = MS Severity Score; N = number; PP = primary progressive; RR = relapsing-remitting; SP = secondary progressive; VZV = varicella zoster virus. Means and SDs are shown unless otherwise specified.

compared with spouses and their old siblings (figure 2A). There was no association between high VZV antibody titers and the study groups (figure 2B). EBNA-1 and VZV

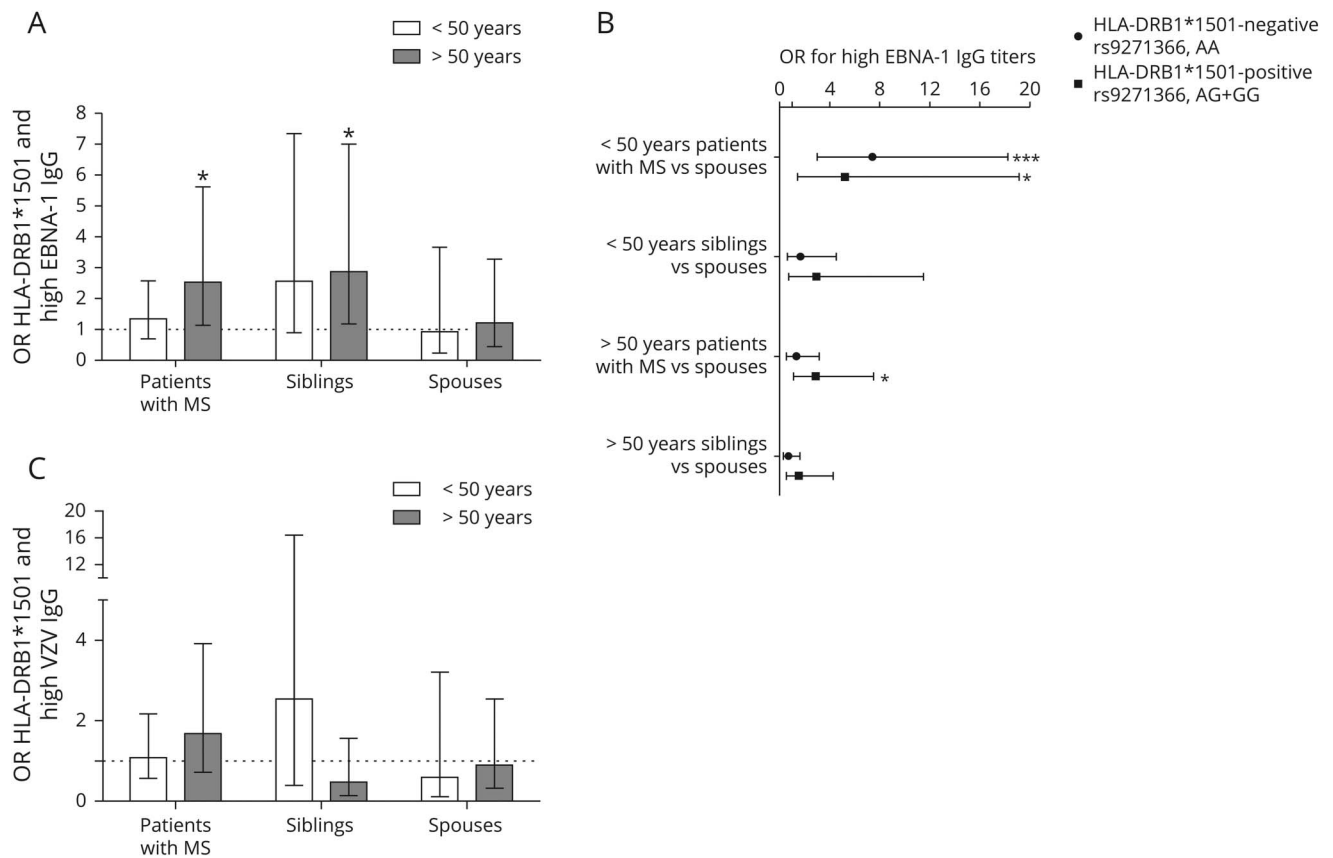

antibody titers were further not associated with gender, clinical disease course, or disease duration (data not shown).

Figure 2 Patients with MS and their siblings have increased risk of high EBNA-1 titers compared with spouses

(A) OR for high EBNA-1 IgG titers (>75th percentile) is increased in patients with MS in both age categories and siblings younger than 50 years of age compared with spouses, suggesting that patients with MS and their siblings are more likely to have higher EBNA-1 IgG titers compared with spouses. (B) No differences in OR for high VZV IgG titers were found between patients with MS and siblings in comparison to the spouses. ORs were calculated by means of logistic regression analysis and GLM were used for between-group comparisons with Bonferroni-corrected and adjusted *p*-values for gender, disease status, and household. The whiskers indicate 95% CI. Dashed line in each graph represents the reference group (spouses). EBNA-1 = EBV nuclear antigen 1; GLM = generalized linear model; IgG = immunoglobulin; VZV = varicella zoster virus.

Figure 3 *HLA-DRB1*1501* carriership is associated with high EBNA-1 IgG titers

(A) ORs for the association between *HLA-DRB1*1501* carriership and high EBNA-1 IgG titers were calculated for patients with MS, siblings, and spouses in 2 age categories. *HLA-DRB1*1501* carriership is associated with high EBNA-1 IgG titers in old patients with MS and siblings. (B) OR for high EBNA-1 IgG titers (>75th percentile) is increased in young patients with MS vs spouses in both *HLA-DRB1*1501*-positive and negative individuals. In older patients with MS compared with controls, OR for high EBNA-1 IgG titers is only increased in *HLA-DRB1*1501*-positive individuals. (C) *HLA-DRB1*1501* is not associated with high VZV IgG titers in all study groups. Logistic regression analyses were performed to calculate ORs, and GLM was used for between-group comparisons with Bonferroni corrected and adjusted *p*-values for gender, disease status and household. The whiskers indicate 95% CI. EBNA-1 = EBV nuclear antigen 1; GLM = generalized linear model; IgG = immunoglobulin; VZV = varicella zoster virus.

HLA-DRB1*1501 carriership is associated with high EBNA-1 IgG in older patients with MS and their siblings

The risk allele (G allele) frequency of the *HLA-DRB1*1501* tagging SNP (rs9271366) was higher in patients with MS (39%; OR = 3.1 95% CI 2.2–4.4) and siblings (28%; OR = 1.9 95% CI 1.3–2.8) when compared with spouses (17%). *HLA-DRB1*1501* was significantly associated with MS (OR = 4.2, 95%CI 2.7–6.6, adjusted *p* = 7.4×10^{-10}). In both patients with MS and study subjects without MS, *HLA-DRB1*1501* was associated with elevated EBNA-1 IgG levels (OR = 1.6 95% CI 1.0–2.6, adjusted *p* = 4.4×10^{-2} and OR = 2.2, 95% CI 1.4–3.6 adjusted *p* = 2.0×10^{-3} , respectively). By contrast, VZV IgG titers were not associated with *HLA-DRB1*1501*.

*HLA-DRB1*1501* risk genotype was associated with high EBNA-1 IgG titers in older patients with MS and older siblings (figure 3A).

OR for high EBNA-1 IgG titers was increased in young patients with MS vs spouses irrespective of *HLA-DRB1*1501*

carriership (figure 3B). In older patients with MS compared with controls, OR for high EBNA-1 IgG titers is only increased in *HLA-DRB1*1501*-positive individuals (figure 3, A and B).

In the *HLA-DRB1*1501*-negative group (AA genotype), young patients with MS had higher EBNA-1 IgG titers than elderly patients with MS (OR = 2.7, 95% CI 1.1–6.1, adjusted *p* = 1.4×10^{-2}). In addition, young patients with MS had higher EBNA-1 IgG titers than siblings (OR = 4.4, 95% CI 1.7–11.2, adjusted *p* = 2.0×10^{-3}) and spouses (OR = 7.4, 95% CI 3.0–18.3, adjusted *p* = 1.4×10^{-5}).

There was no association between *HLA-DRB1*1501* and high VZV IgG titers (>75th percentile) in all study groups in both age categories (figure 3C).

HLA-A*02 is not associated with MS and EBNA-1 IgG titers

The *HLA-A*02* tagging SNP (rs6457110) was not associated with MS in our study (OR = 0.9 95% CI 0.6–1.2, *p* = 0.4 adjusted for age, gender, household, and *HLA-DRB1*1501*).

Figure 4 The risk of high EBNA-1 IgG is associated with age, *HLA-DRB1*1501* carriership, having MS, or being a family member of a patient with MS

The risk of high EBNA-1 IgG is associated with age, having MS, or being a family member of a patient with MS, and *HLA-DRB1*1501* carriership. EBNA-1 = EBV nuclear antigen 1; IgG = immunoglobulin.

The *HLA-A*02* tagging SNP was also not associated with EBNA-1 IgG and VZV titers when stratified for all study groups and age categories (data not shown).

Risk for high EBNA-1 IgG titers is increased in patients with MS, *HLA-DRB1*1501* carriers, and young siblings of patients with MS

Finally, we performed a multivariate analysis to assess the individual effect of having MS or being a family member of a patient with MS, and having *HLA-DRB1*1501*, stratified for age. In both age categories, having MS is an independent risk factor for high EBNA-1 IgG levels, and this effect is independent of *HLA-DRB1*1501*. In addition, being a young family member of a patient with MS increases the risk of abundant EBNA-1 IgG (figure 4). These results underscore the importance of the host genetics on the humoral immune response against EBV. Moreover, it indicates the importance of other genetic factors, for example, other polymorphisms and epigenetic changes over time, contributing to the humoral immune response against EBV in MS.

Discussion

We showed a gradient in EBNA-1 IgG being the highest in patients with MS, intermediate in their siblings, and the lowest in spouses. Congruent with our results, Comabella et al.¹⁴ found an increased IgG response to EBNA-1 in patients with MS compared with healthy siblings without a biologically unrelated control group. A very small study using a nonlinear EBNA-1 IgG quantification method assessing patients with MS and their siblings in comparison to unrelated controls showed the results comparable with our study.¹⁷

The observed EBNA-1 IgG titer gradient in our study suggests a genetic contribution of MS-related SNPs to EBNA-1 IgG titers. Indeed, in previous studies, first-degree family members of patients with MS showed to have higher genetic load for MS-associated risk SNPs compared with spouses.^{4,5} We confirmed that *HLA-DRB1*1501* carriership significantly associates with high EBNA-1 IgG titers. A recent study showed that *HLA-DRB1*1501* carriership also in healthy controls, fully unrelated to patients with MS, is associated with enhanced EBNA-1 IgG levels.²³ The high prevalence of *HLA-DRB1*1501* in patients with MS, intermediate in siblings, and low in spouses could partly explain the gradient observed in EBNA-1 IgG titers in the 3 groups. After stratification for *HLA-DRB1*1501*, the observed gradient was still present in young patients with MS, siblings and spouses. This implies that *HLA-DRB1*1501* is not the only player for the generation of the anti-EBV immune response in young patients with MS. The *HLA-A*02* tagging SNP was not associated with the EBNA-1 IgG titers. Likely, other genetic factors besides *HLA-DRB1*1501* contribute to increased EBNA-1 IgG response.^{24,25} Next to shared genetics, shared environment between patients with MS and their siblings in early life, when EBV infection typically occurs, might partly be responsible for the found EBNA-1 IgG gradient.

Moreover, we found that high EBNA-1 titers were associated with low age. When stratified into study groups, EBNA-1 IgG was higher in young patients with MS compared with elderly patients with MS. This could be due to a particular phenomenon called immunosenescence, i.e., a gradual negative dysregulation of the immune system in the elderly.²⁶ There is overwhelming evidence that the amount of antibodies induced after an immunization response is strongly reduced with physiologic aging and that titers decline occur more rapidly in elderly.^{27,28} In our study, we found that particularly in elderly patients and their elderly siblings, high EBNA-1 IgG titers were associated with the presence of the *HLA-DRB1*1501*. This may suggest that a certain genetic make-up is needed to react adequately to the EBV infection in elderly. Indeed, *HLA-DRB1*1501* is strongly correlated with EBNA-1 IgG.²⁹ There was a limitation to our study. Because of a moderate sample size, we limited ourselves to testing only *HLA-DRB1*1501* and *HLA-A*02* loci in the genetic association analyses in relation to viral titers. Because of a suggestive genetic contribution on the EBNA-1 IgG response, it would be interesting to assess how non-HLA MS risk SNPs are involved in this process.

In summary, our study showed that EBNA-1 IgG titers were highest in patients with MS, intermediate in siblings, and low in spouses, which suggests a strong genetic contribution on the EBNA-1 response that is partially associated with *HLA-DRB1*1501*. Correcting for *HLA-DRB1*1501* did not abrogate this association, which suggests that additional genetic factors may contribute to this gradient. Further large genetic studies assessing MS genetics and EBNA-1 IgG responses are

needed to determine which MS risk SNP are contributing to the enhanced EBNA-1 IgG response in MS. In addition, EBNA-1 IgG titers were higher in young patients with MS compared with elderly patients with MS. To study the complex interaction between environmental and genetic factors, age needs to be considered. Potentially, this relates to the predominant relapsing-remitting disease progression in young compared with the more progressive disease in older patients with MS.

Acknowledgment

The authors would like to thank all patients with MS and their families for their participation in this study. A special thank you to Janienne Klaasse and Sandra M.J. Scherbeijn for sample handling and technical assistance with the quantification of the antiviral titers.
