Chest CT features  
Clinical severity  
Meta-analysis

## ABSTRACT

**Background:** It remains unclear whether a specific chest CT characteristic is associated with the clinical severity of COVID-19. This meta-analysis was performed to assess the relationship between different chest CT features and severity of clinical presentation in COVID-19.

**Methods:** PubMed, Embase, Scopus, web of science databases (WOS), Cochrane library, and Google scholar were searched up to May 19, 2020 for observational studies that assessed the relationship of different chest CT manifestations and the severity of clinical presentation in COVID-19 infection. Risk of bias assessment was evaluated applying the Newcastle-Ottawa Scale. A random-effects model or fixed-effects model, as appropriately, were used to pool results. Heterogeneity was assessed using Forest plot, Cochran's Q test, and I<sup>2</sup>. Publication bias was assessed applying Egger's test.

**Results:** A total of 18 studies involving 3323 patients were included. Bronchial wall thickening (OR 11.64, 95% CI 1.81–74.66) was more likely to be associated with severe cases of COVID-19 infection, followed by crazy paving (OR 7.60, 95% CI 3.82–15.14), linear opacity (OR 3.27, 95% CI 1.10–9.70), and GGO (OR 1.37, 95% CI 1.08–1.73). However, there was no significant association between the presence of consolidation and severity of clinical presentation (OR 2.33, 95% CI 0.85–6.36). Considering the lesion distribution bilateral lung involvement was more frequently associated with severe clinical presentation (OR 3.44, 95% CI 1.74–6.79).

**Conclusions:** Our meta-analysis of observational studies indicates some specific chest CT features are associated with clinical severity of COVID-19.

## 1. Introduction

Corona Virus Disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), has been spreading throughout the world threatening the global health condition. COVID-19 infection causes a spectrum of respiratory illness ranges from a mild pneumonia to the critically ill and fatal cases of Acute Respiratory Distress Syndrome (ARDS).<sup>1–3</sup> The timely identification and successful treatment of severe and critical cases of COVID-19 are essential to reduce the complications and mortality of the disease. Many studies aimed to find the disease severity-related factors in the clinical practice resulting in identification of some clinical, laboratory, and imaging factors as the predictors of disease severity.<sup>3,4</sup>

Chest CT scan is a frequently used imaging tool for the early detection and monitoring of patients affected by COVID-19 due to the facts

that it is relatively easy to perform and can produce fast diagnosis. Typical CT features of confirmed COVID-19 pneumonia have been shown to be helpful in evaluation of the severity and extent of disease.<sup>5,6</sup> Multilobular infiltration, accounted for the highest score in MuLBSTA system (multilobular infiltration, hypo-lymphocytosis, bacterial co-infection, smoking history, hypertension, and age) for predicting the mortality in patients with viral pneumonia,<sup>7</sup> has been more frequently reported in patients with severe and critical types of COVID-19 infection compared to the common types.<sup>3,5,6</sup> The detailed imaging features in various clinical types of COVID-19 infection have been investigated in several studies indicating significant differences between common and severe cases.<sup>3,6,8</sup>

Exploring the chest CT features in the spectrum of clinical presentation of the COVID-19 infection can help us to predict outcome and support clinical decision making. Although several studies indicated

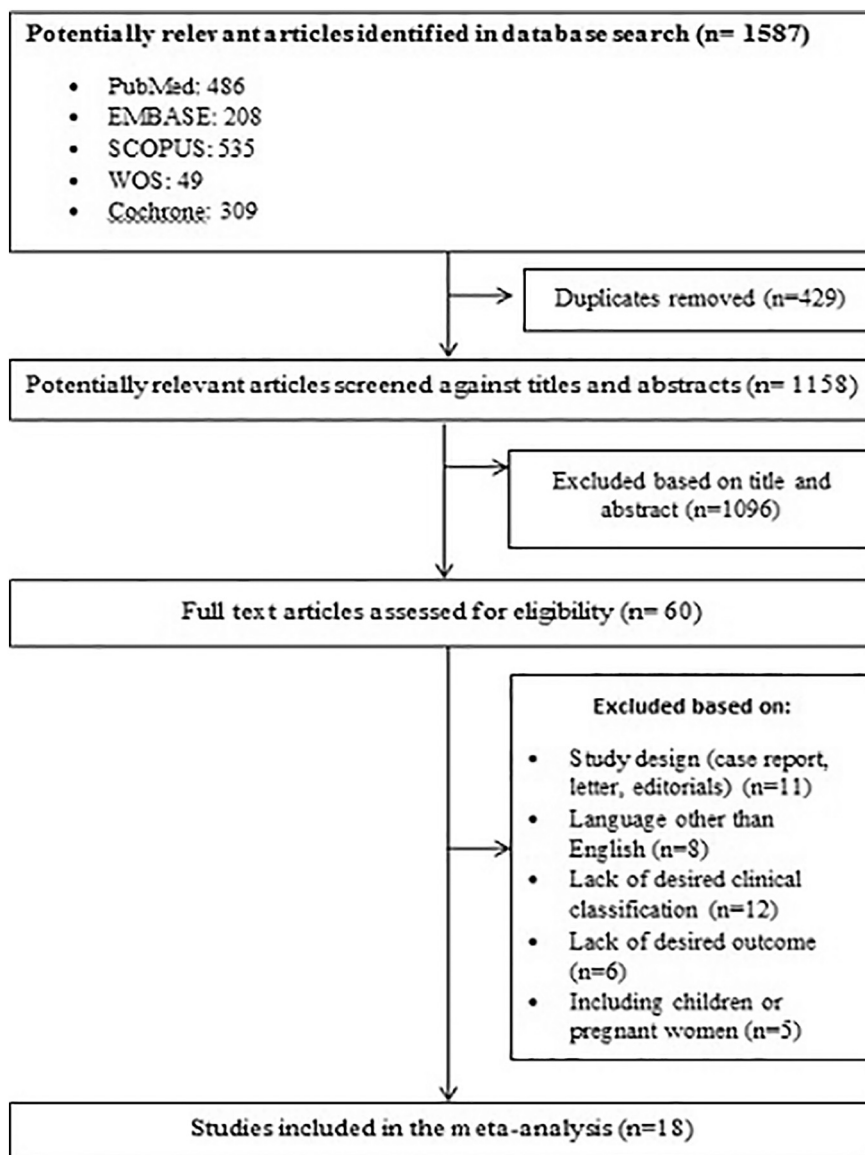

Fig. 1. Flow diagram of literature search and study selection.

some CT features are associated with severe types of COVID-19 infection, as far as we know, there is no meta-analysis of these findings. Thus, we aimed to quantitatively summarize results from published studies to date to identify the CT features which determine the severity of COVID-19 infection.

## 2. Methods

### 2.1. Search strategy and selection criteria

We searched for studies of any design and in any setting that included patients with COVID-19 infection and reported disease severity as well as chest CT characteristics of the patients. We initially did not limit our study by language.

The aim of this systematic review was to quantitatively assess the association of clinical severity of COVID-19 infection with the chest CT characteristics. The clinical severity of the disease defined as common type, which included all patients with fever, cough, or other respiratory symptoms with or without CT manifestation of pneumonia, and severe type, which included the patients with any of the following condition: 1) respiratory rate  $\geq 30$  breaths per minute; 2) finger of oxygen saturation

$\leq 93\%$  in a resting state; 3) arterial oxygen tension (PaO<sub>2</sub>)/inspiratory oxygen fraction (FiO<sub>2</sub>)  $\leq 300$  mmHg (1 mmHg=0.133 kPa); 4) respiratory failure and mechanical ventilation requirement; 5) shock; 6) patients with other organ failure needed intensive care unit (ICU) monitoring treatment.<sup>9</sup>

We searched PubMed, Embase, Scopus, web of science databases (WOS), Cochrane library, and Google scholar from January 1, 2020 up to May 19, 2020 applying the following search terms: Coronavirus OR covid-19 OR 2019-CoV OR CoV OR severe acute respiratory syndrome coronavirus 2 OR SARS-CoV-2 AND CT scan OR Computed tomography OR CT image\* OR CT find\* OR CT manifestation\* OR CT Feature\* OR Chest CT AND Severity OR Refractory OR Critical OR Emergency OR ICU admission.

### 2.2. Data extraction

We screened titles and abstracts, reviewed full texts, extracted data, and assessed risk of bias by two authors independently. We resolved disagreements by consensus. We included the studies met the following eligibility criteria: 1) the publications were original articles with full text; 2) the studies included patients with laboratory- confirmed COVID-

19 infection; 3) the studies reported information on clinical severity of the disease; 4) at least one of the chest CT features of COVID-19 has been reported. Studies were excluded if 1) the full text was not in English; 2) the studied populations were children or pregnant women; 3) the study was case report or clinical trial.

We extracted data for study identifier, study sample size, mean or median age of the participants, gender distribution, disease severity classification, results of chest CT imaging features, the number of patients with each corresponding imaging features considering disease severity classification.

### 2.3. Data analysis

All Statistical analyses were performed using Stata version 14 (StataCorp. 2015. Stata Statistical Software: Release 14. College Station, TX: StataCorp LP.). We employed “metaprop” command to calculate the pooled prevalence estimates of chest CT features with 95% confidence. The associations between chest CT features and severity of disease, were expressed as odds ratios (ORs) and 95% confidence intervals (CIs). Heterogeneity among the primary studies was evaluated by the forest plots, Cochran’s Q statistic, and  $I^2$  statistic. A random-effects model was used if heterogeneity was high ( $I^2 > 50%$ ); otherwise, a fixed-effects model was applied. Also, the publication bias was formally tested with Egger’s regression asymmetry tests to determine the asymmetry of the funnel plots, where  $p < 0.10$  was considered as evidence of bias.

### 3. Results

#### 3.1. Literature retrieval

A total of 1587 related records have been identified in the initial retrieval. Upon removal of duplication, 1158 records have been screened against the title and abstract. Full text of 60 studies has been assessed for eligibility. We identified 18 studies for our systematic review. Studies were all observational in nature. All included studies were retrospective but for one that was prospective.<sup>10</sup> These 18 studies fulfilled criteria for including in the meta-analysis (Fig. 1, Table 1).

#### 3.2. Characteristics of the included studies and risk of bias quality assessment

The total of 18 articles included 3323 patients with laboratory-confirmed COVID-19 infection. All included articles reported data on comparison of chest CT features of the COVID-19 infection in patients with various disease severities, but for two studies<sup>1,11</sup> that included only common type of COVID-19 infection. Different features of CT imaging had been reported in the included studies. However, the frequently reported features were ground glass opacity (GGO), reported in 15 studies,<sup>1–6,8,11–19</sup> consolidation, reported in 10 studies,<sup>1,3,5,6,11,12,15–18</sup> linear opacity, reported in 4 studies,<sup>1,3,6,17</sup> bronchial wall thickening, reported in 3 studies,<sup>5,6,15</sup> crazy paving, reported in 2 studies,<sup>6,17</sup> and bilateral lung involvement, reported in 15 studies<sup>2–6,8,10,12–15,17–20</sup> (Table 1). Risk of bias was generally low after considering the observational designs (Supplementary Table 1).

Fig. 3. Forest plot showing the association between consolidation in chest CT images and severity of clinical presentation.

### 3.3. Pattern of lesions

Twelve studies were included to explore the association between the presence of GGO in CT images and clinical severity of the disease. Compared with the common type, the pooled OR for the presence of GGO in CT images of patients with severe disease was 1.37 (95% CI 1.08–1.73,  $I^2 = 0.0\%$ ,  $P$  for heterogeneity = 0.486) (Fig. 2). Eight studies were included to explore the association between the presence of consolidation in CT images and clinical severity of the disease. The pooled OR for the presence of consolidation in CT images of patients with severe disease, compared to the common type, was 2.33 (95% CI 0.85–6.36,  $I^2 = 74.5\%$ ,  $P$  for heterogeneity = 0.000) (Fig. 3). Three studies were included to explore the association between the presence of linear opacity in CT images and clinical severity of the disease. Compared with the common type, the pooled OR for the presence of linear opacity in CT images of patients with severe disease was 3.27 (95% CI 1.10–9.70,  $I^2 = 73.8\%$ ,  $P$  for heterogeneity = 0.022) (Fig. 4). Three studies were included to explore the association between the presence of bronchial wall thickening in CT images and clinical severity of the disease. The pooled OR for the presence of bronchial wall thickening in CT images of patients with severe disease, compared to the common type, was 11.64 (95% CI 1.81–74.66,  $I^2 = 81.8\%$ ,  $P$  for heterogeneity = 0.004) (Fig. 5). Two studies were included to explore the association between the presence of crazy paving in CT images and clinical severity of the disease. Compared with the common type, the pooled OR for the presence of crazy paving in CT images of patients with severe disease was 7.60 (95% CI 3.82–15.14,  $I^2 = 84.3\%$ ,  $P$  for heterogeneity = 0.012) (Fig. 6). Substantial between-study heterogeneity was

shown in results for three patterns of lesion namely, consolidation, linear opacity, and bronchial wall thickening.

### 3.4. Lesion distribution

Bilateral lung involvement has been explored in thirteen included studies. Compared with the common type, the pooled OR for the presence of bilateral lung involvement in CT images of patients with severe disease was 3.44 (95% CI 1.74–6.79,  $I^2 = 63.9\%$ ,  $P$  for heterogeneity = 0.001) (Fig. 7). There was no evidence for substantial between study heterogeneity in results for bilateral lung involvement.

### 3.5. Assessment of publication bias

Begg’s and Egger’s regression tests provided no evidence of substantial publication bias except for GGO ( $P < 0.1$  for both tests).

## 4. Discussion

Our systematic review and meta-analysis of 18 studies involving 3323 patients provides comprehensive information on the chest CT features associated with the severe cases of COVID-19 infection. Bronchial wall thickening was more likely to be associated with severe cases of COVID-19 infection, followed by crazy paving, linear opacity, and GGO. However, there was no significant association between the presence of consolidation and severity of clinical presentation. Considering the lesion distribution, as expected, bilateral lung involvement was more frequently associated with severe clinical presentation.

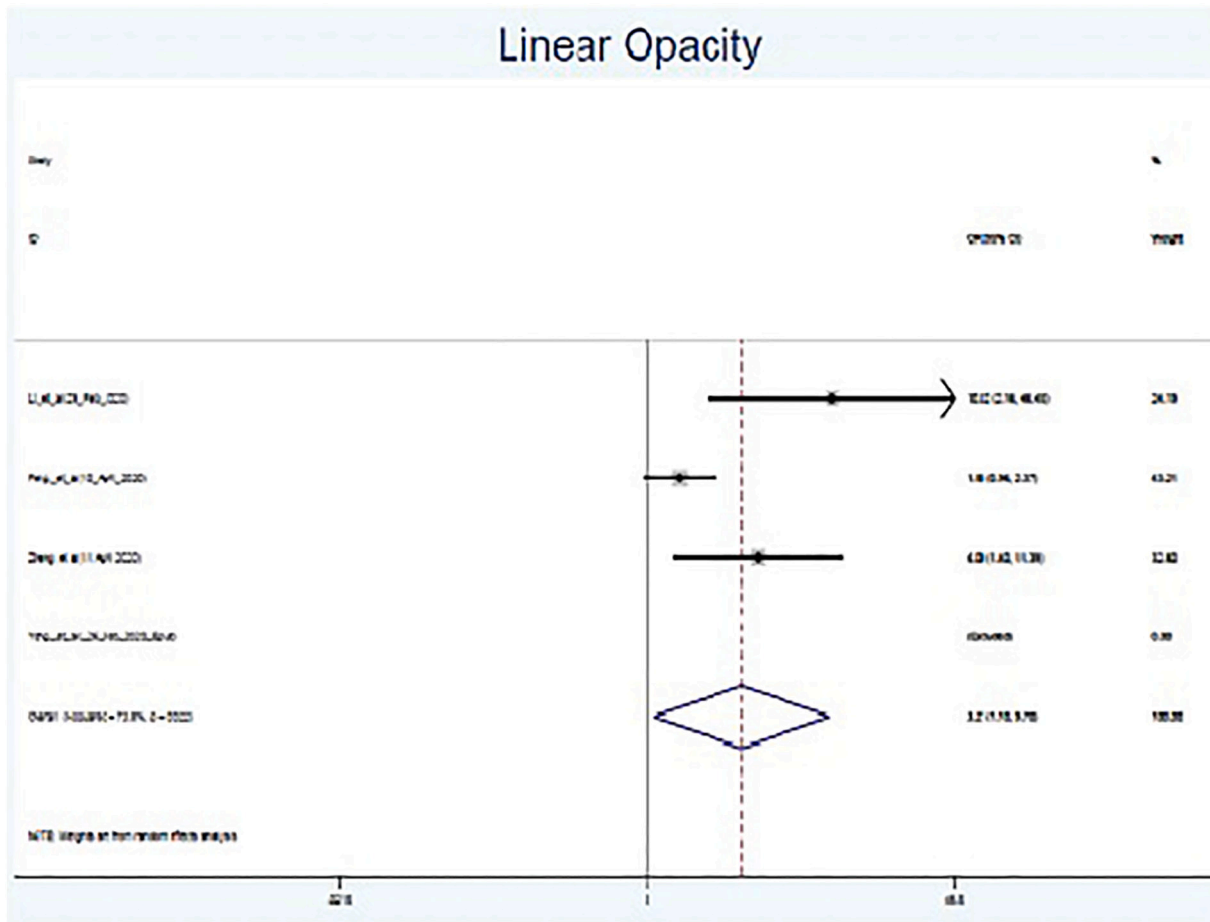

Fig. 4. Forest plot showing the association between linear opacity in chest CT images and severity of clinical presentation.

4.1. GGO

GGO indicates an area of hazy increased lung opacity, less opaque than consolidation, through which vessels and bronchial structures may still be obscured. Although GGO is the most common CT feature of COVID-19 pneumonia, most studies did find no statistically significant difference in the presence of GGO between severe and common cases of COVID-19. Nevertheless, the meta-analysis of these studies indicated a 37% increase in the risk of the presence of GGO in severe cases compared to the common type (Fig. 2). Since the GGO has been known as the typical early CT feature of COVID-19 pneumonia, it is advised that the small lesions, and especially new lesions, that contained an area of GGO requires follow-up to eliminate the possibility of COVID-19 pneumonia in high-risk subjects.<sup>21</sup>

4.2. Consolidation

Consolidation is often a middle-to-late stage feature in pulmonary infection. One study investigated the time course of lung changes at chest CT concluded the typical COVID-19 mainly starts with small GGOs in the lower lobes, which then develops into the crazy-paving pattern and subsequent consolidation.<sup>22</sup> Although some studies indicated the association of consolidation with the severity of COVID-19 infection, others failed to show this association.<sup>5,15,23,24</sup> The pooled analysis of these studies did not demonstrate any significant association between the presence of consolidation and the severity of clinical manifestations (Fig. 3). Consolidated tissue is more radio-opaque than normally aerated lung parenchyma, indicating the alveoli are completely filled by inflammatory exudation, hemorrhage, or pus. This feature could reflect

the severity of lung involvement. The reason why this meta-analysis could not find a significant association between the presence of consolidation on the chest CT and severity of clinical presentation might be explained by the fact that in the included studies the chest CT scan had been performed at the early stage of the infection while consolidation has been demonstrated to be noted on chest CT during disease progression.<sup>3</sup> Thus, the time point from the onset of disease at which the chest CT is performed has a critical role in demonstrating the consolidation.

4.3. Linear opacity

The linear opacity, occurred in different interstitial lung disease, is typical for an evolution towards organizing pneumonia. Pooled analysis of studies evaluated the presence of linear opacity among patients with various disease severities indicated this finding is more likely to be observed in severe cases of COVID-19 than that observed in the common type (Fig. 4). Temporal analyzing of multiple chest CT scans demonstrated a specific pattern during which linear opacity, observed 7–31 days after disease onset, indicates sub-segmental atelectasis or secondary organizing pneumonia. This pattern might be representative of irreversible fibrosis.<sup>21,25</sup>

4.4. Bronchial wall thickening

Abnormal thickening of bronchial walls, arisen from various pathological entities, usually indicates inflammation of the airways. A few studies investigated the association of bronchial wall thickening with the severity of COVID-19 infection, resulting in the conflicting findings.

Fig. 5. Forest plot showing the association between bronchial wall thickening in chest CT images and severity of clinical presentation.

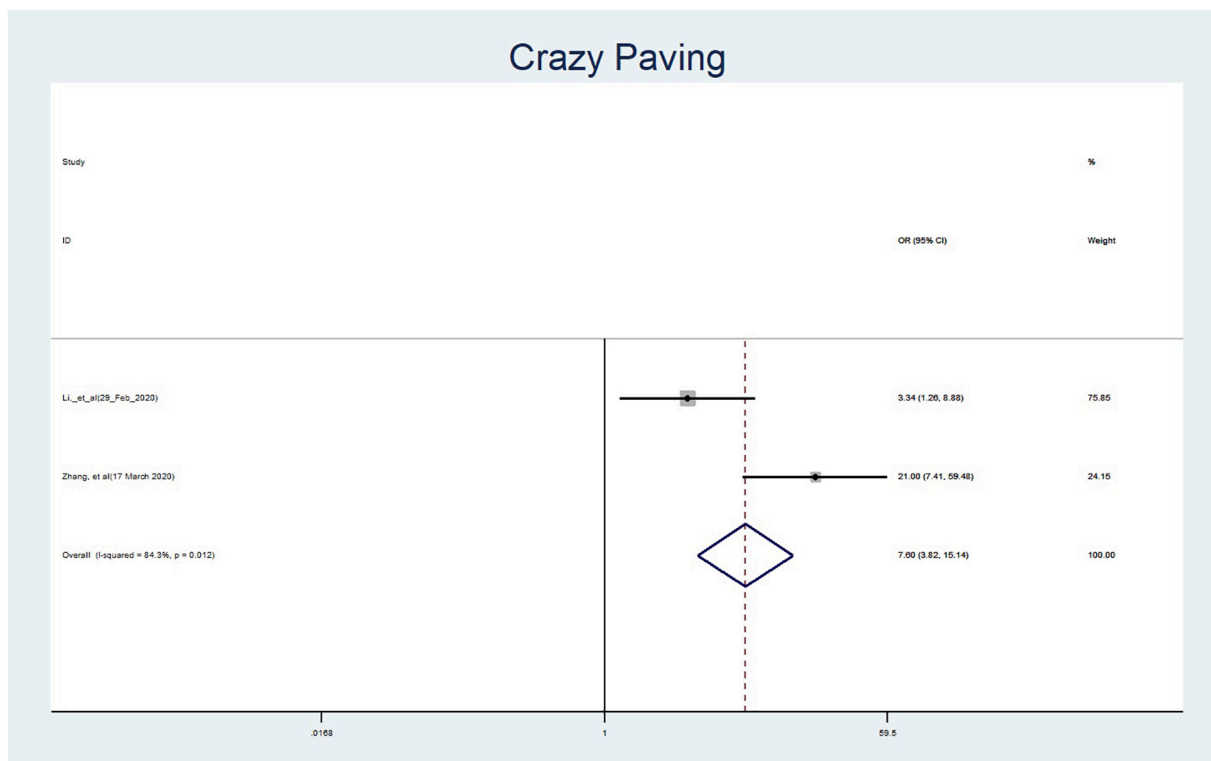

Fig. 6. Forest plot showing the association between crazy paving in chest CT images and severity of clinical presentation.

Fig. 7. Forest plot showing the association between bilateral lung involvement in chest CT images and severity of clinical presentation.

Pooled analysis of these findings indicated significantly higher odds of bronchial wall thickening in severe cases of COVID-19 compared to the common type (Fig. 5). Airway wall thickening, which has been attributed to the high level of Vascular endothelial growth factor (VEGF), is suggested to reflect the duration and severity of disease and the degree of airflow obstruction in asthma.<sup>26,27</sup> On the other hand, recent evidence has revealed an increase in the levels of VEGF in COVID-19 patients,<sup>28</sup> leading to the use of anti- VEGF medications in severe cases of COVID-19 infection in the context of clinical trial (<https://clinicaltrials.gov/ct2/show/NCT04275414>). The association of bronchial wall thickening with the severity of COVID-19 infection in this meta-analysis could be explained by the possible role of VEGF in the development and severity of bronchial wall thickening in COVID-19.

#### 4.5. Crazy paving

Crazy paving defined as thickened interlobular septa and intralobular lines superimposed on diffuse ground glass changes.<sup>29,30</sup> Several studies indicated as COVID-19 progresses this pattern can be noted on CT.<sup>22,31</sup> Studies investigated the temporal changes of the CT features and its relation to disease onset showed crazy paving was frequently observed 10–14 days after the onset of the initial symptoms,<sup>32,33</sup> however, the presence of crazy paving at early stages might be an indicator of rapid progression of the disease with poor prognosis.<sup>32</sup> Moreover, a recent review concluded that crazy paving can be a signal of COVID-19 entering a progressive stage.<sup>34</sup> The results of this meta-analysis support the association of crazy paving feature on CT images with the severity of clinical outcomes suggesting this pattern

could be considered as an alert in the management of patients.

#### 4.6. Bilateral lung involvement

Many studies investigated the distribution of lung involvement in patients with various severities indicating the conflicting results. However, analysis of the pooled data showed bilateral lung involvement is 3.44 times more likely to be observed in severe cases of COVID-19 compared to the common type (Fig. 7). Irrespective of the disease severity, some previous studies indicated that bilateral lung involvement is the most anatomic distribution of COVID-19 pneumonia.<sup>35,36</sup>

#### 4.7. Strength and limitation

To the best of our knowledge, this meta-analysis is the first one that evaluated chest CT features associated with clinical severity of COVID-19 infection. Moreover, high quality studies with a relatively large number of participants have been included in this study. In addition, all studies included in this meta-analysis followed the same classification for determination of disease severity.

However, this study has several limitations. First of all some features of chest CT imaging have not been included in the meta-analysis. Furthermore, some patients might have comorbidities such as chronic obstructive pulmonary disease (COPD) that could affect imaging appearance. Moreover, almost all included studies were retrospective that the results might be influenced by the confounding factors. In addition, because of different CT scanners and interpreting radiologists, the reported imaging features might be variable across sites. Lastly, this

meta-analysis indicated a significant heterogeneity between the studies regarding some CT features. Moreover, results on GGO might be affected by the publication bias.

## 5. Conclusion

In summary, our meta-analysis of the observational studies shows bronchial wall thickening, crazy paving, linear opacity, and GGO are more likely to be associated with the severe type of COVID-19 compared to the common type. However, consolidation in chest CT was not associated with the severity of clinical presentation. Regarding the lesion distribution, as expected, bilateral lung involvement was more likely to be observed in severe cases rather than common ones. Identification of the chest CT images associated with severe cases of COVID-19 is useful for early diagnosis and timely treatment of the severe and fatal cases of COVID-19 infection.
