Reversible nanocluster structure transformation between face-centered cubic and icosahedral isomers†

Xi Kang,^a Li Huang,^b Wei Liu,^b Lin Xiong,^c Yong Pei,^c Zhihu Sun,^{*b} Shuxin Wang,^{*a} Shiqiang Wei^b and Manzhou Zhu^{*a}

Structural transformations between isomers of nanoclusters provide a platform to tune their properties and understand the fundamental science due to their intimate structure–property correlation. Herein, we demonstrate a reversible transformation between the face-centered cubic (FCC) and icosahedral isomers of Pt₁Ag₂₈ nanoclusters accomplished in the ligand-exchange processes. Ligand-exchange of 1-adamantanethiolate protected Pt₁Ag₂₈ by cyclohexanethiolate could transform the FCC kernel to the icosahedral isomer. Interestingly, the icosahedral Pt₁Ag₂₈ could be reversibly transformed to the FCC configuration when the cyclohexanethiolate ligand is replaced again by 1-adamantanethiolate. A combination of UV-vis absorption, mass spectrometry, photo-luminescence and X-ray absorption fine structure unambiguously identifies that the FCC-to-icosahedral structure transformation of Pt₁Ag₂₈ involves two distinct stages: (i) ligand-exchange induced outmost motif transformation and (ii) abrupt innermost kernel transformation. As a result of this structural transformation, the emission wavelength of Pt₁Ag₂₈ red-shifts from 672 to 720 nm, and the HOMO–LUMO energy gap reduces from 1.86 to 1.74 eV. This work presents the first example of nanocluster isomers with inter-switching configurations, and will provide new insights into manipulating the properties of nanoclusters through controllably tuning their structures.

1 Introduction

Nanoclusters, with the advantages of precise compositions and well-defined structures, provide an exciting opportunity to grasp the structure–property correlation at the atomic level.^{1,2} The quantum size effect of nanoclusters endows them with a plethora of properties, such as photo-luminescence (PL), catalysis, chirality, and magnetism, to name a few.^{1,2} The property manipulation at the atomic level has long been a hot

topic, and has allowed a series of nanoclusters with controllable chemical–physical properties to be produced.^{1f–h,2g,i,k,l}

Isomerism is being intensely pursued in nanoscience, and has been exploited for tailoring the performances of nanoparticles.³ However, understanding the isomerism phenomenon at the atomic level has been largely impeded due to the poly-disperse sizes as well as the uncertain surface coordination modes of nanoparticles.^{1a,b,3b} The precise structures of nanoclusters make it possible to fully grasp the isomerism phenomenon.^{4–6} Although stereoisomerism has been extensively studied in the nanocluster field (that is, obtaining chiral–optical nanoclusters *via* the separation of left- and right-handed isomers),^{4,5} structural isomerism remains rare. Up to now, only a few structural isomers in the nanocluster range have been observed (*e.g.*, Au₂₈(SR)₂₀, Au₃₈(SR)₂₄, and Au₅₂(SR)₃₂).^{6a,c–f} Different structure-dependent properties (*e.g.*, optical absorption, catalytic activity, and thermal stability) have been investigated on the basis of these nanocluster isomers.^{5f,6} In addition, experimental and theoretical efforts in exploring the isomerism effect on atomic arrangement and properties of nanoclusters should be continued because such findings enable us to fully grasp the structure–property correlation, and thus help us to design new nanoclusters with unique functions.^{5f,6}

Meanwhile, accompanied by the structure determination of nanoclusters resolved by single-crystal X-ray crystallography

(SCXC), several efforts have been made for grasping the size-growth and structure-transformation modes from small complexes to nanoclusters, then to large nanoparticles.^{14,17} Icosahedron and face-centered cubic (FCC) are the two most common configurations of nanocluster kernels. The structural transformation from an icosahedral to FCC configuration or its reverse process has been reported recently in the nanocluster field.^{6d,8} For instance, ligand-exchanging Au₂₅(S-C₂H₄Ph)₁₈ with excess ^tBuPh-SH changes the icosahedral configuration of the Au₁₃ kernel into a FCC configuration.^{6d} Besides, the existence of Me₂PhSH can transform Au₄₄(S-Ph^tBu)₂₈ into Au₄₄(S-PhMe₂)₂₆, where the kernel changes from the FCC to the icosahedral configuration.^{8a} However, for nanocluster isomer systems, to the best of our knowledge, the structural transformation from the FCC to icosahedron or its reverse process, not to mention the reversible transformation between these two configurations, remains incomplete. Such a shortage impedes the full understanding of nanocluster isomerism in terms of structure-transformation modes and structure–property correlation.

In the current work, a reversible transformation has been accomplished between FCC and icosahedral isomers of Pt₁Ag₂₈ nanoclusters. The ligand-exchange method is herein exploited for fulfilling the reversible transformation between Pt₁Ag₂₈(S-Adm)₁₈(PPh₃)₄ (**Pt₁Ag₂₈-1**, where S-Adm represents 1-adamantanethiol) with a FCC Pt₁Ag₁₂ kernel and Pt₁Ag₂₈(S-*c*-C₆H₁₁)₁₈(PPh₃)₄ (**Pt₁Ag₂₈-2**, where S-*c*-C₆H₁₁ represents cyclohexanethiol) with an icosahedral Pt₁Ag₁₂ kernel. ESI-MS, PL and EXAFS results are combined to demonstrate that the configurational transformation between the FCC and the icosahedron contains two distinct stages: the motif transformation process and kernel transformation process, where the latter transformation is induced by the former one. Accompanied by the structural transformation (from **Pt₁Ag₂₈-1** to **Pt₁Ag₂₈-2**), the emission wavelength red-shifts from 672 nm to 720 nm, and the HOMO–LUMO energy gap reduces from 1.86 eV to 1.74 eV.

2 Experimental methods

2.1 Materials

All chemicals including silver nitrate (AgNO₃, 99.9%, metal basis), hexachloroplatinic(IV) acid (H₂PtCl₆·6H₂O, 99.9% metal basis), triphenylphosphine (PPh₃, 99%), 1-adamantanethiol (Adm-SH, C₁₀H₁₅SH, 99%), cyclohexanethiol (C₆H₁₁-*c*-SH, 99%), sodium borohydride (NaBH₄, 99.9%), styrene (C₆H₅-C₂H₃, 99.5%), potassium carbonate (K₂CO₃, 99.5%), methylene chloride (CH₂Cl₂, HPLC grade), methanol (CH₃OH, HPLC), acetic ether (CH₃COOC₂H₅, HPLC), ether ((C₂H₅)₂O, HPLC), and toluene (C₆H₅-CH₃, HPLC) were purchased from Sigma-Aldrich and used without further purification. All glassware were thoroughly cleaned with aqua regia (HCl : HNO₃ = 3 : 1 v/v), rinsed with copious pure water, and then dried in an oven prior to use.

2.2 Synthesis of Pt₁Ag₂₈-1 nanoclusters

The synthesis of **Pt₁Ag₂₈-1** nanoclusters was carried out with reference to our previous work.^{8b}

2.3 Converting Pt₁Ag₂₈-1 into Pt₁Ag₂₈-2 nanoclusters

Specifically, 10 mg of **Pt₁Ag₂₈-1** nanoclusters was dissolved in 30 mL of CH₂Cl₂. 300 μL of C₆H₁₁-*c*-SH was added and reacted for 2 hours at 40 °C. After the reaction was complete, the solution was rotavaporated, and then approximately 50 mL of methanol was added to wash the product. The precipitate was dissolved in CH₂Cl₂ giving rise to the solution of **Pt₁Ag₂₈-2** nanoclusters. The yield was about 80% (*i.e.*, 8 mg of **Pt₁Ag₂₈-2** was obtained).

2.4 Converting Pt₁Ag₂₈-2 into Pt₁Ag₂₈-1 nanoclusters

Specifically, 10 mg of **Pt₁Ag₂₈-2** nanoclusters was dissolved in 30 mL of CH₂Cl₂. 0.1 g of Adm-SH was added and reacted for 3 minutes at room temperature. After the reaction was complete, the solution was rotavaporated, and then approximately 50 mL of methanol was added to wash the product. The precipitate was dissolved in CH₂Cl₂ giving rise to the solution of **Pt₁Ag₂₈-1** nanoclusters. The yield was about 90% (*i.e.*, 9 mg of **Pt₁Ag₂₈-1** was obtained). Compared with the conversion from **Pt₁Ag₂₈-1** to **Pt₁Ag₂₈-2**, the reverse process is quicker.

2.5 Crystallization of the Pt₁Ag₂₈-2 nanoclusters

Single crystals of **Pt₁Ag₂₈-2** were crystallized by vapor diffusion of ether into the CH₂Cl₂ solution of the nanoclusters over 7 days. For promoting the crystallization, Na⁺(BPh₄)⁻ counterions (molar ratio between clusters and counter-ions was 1 : 2) were added into the CH₂Cl₂ solution. Then black crystals were collected and the structure of the **Pt₁Ag₂₈-2** nanocluster was determined. The CCDC number of the **Pt₁Ag₂₈-2** nanocluster is 1840953.

2.6 Test of the temperature–PL correlation

10 mg of **Pt₁Ag₂₈-1** (or **Pt₁Ag₂₈-2**) was dissolved in 10 mL of CH₂Cl₂/2-CH₃-THF. Then the solutions were cooled to different temperatures and the PL spectra were measured.

2.7 Catalytic performance

For the preparation of catalysts, **Pt₁Ag₂₈-1** (or **Pt₁Ag₂₈-2**) clusters were supported on commercial carbon nanotubes (CNTs; Beijing Bo Yu high-tech new material technology Co., Ltd). The CNTs were first dispersed in toluene, and the nanoclusters were added to the suspension of CNTs under vigorous magnetic stirring. The adsorption of clusters was allowed to proceed overnight. Then the product was separated from the solution by centrifugation. The cluster@CNT composite was dried in a vacuum for 12 h; then, **Pt₁Ag₂₈-1**@CNT and **Pt₁Ag₂₈-2**@CNT catalysts (with a 2 wt% cluster loading) were obtained.

For the catalytic activity test, a 10 mL Schlenk bottle was charged with 0.5 mmol of styrene, 1.5 mmol of TBHP (*tert*-butyl hydroperoxide), 20 mg of cluster@CNT catalyst, 10 mg of K₂CO₃, and 2 mL of toluene. Then the suspension was stirred at 50 °C for 24 hours. The suspension was then centrifuged to remove solids, and the catalytic product was analysed by gas chromatography with an internal standard.

2.8 XAFS (X-ray absorption fine structure spectroscopy) measurements

XAFS measurements at the Pt L₃-edge (11564 eV) were performed at the beamline BL14W1 station of the Shanghai Synchrotron Radiation Facility (SSRF), China. The storage ring of the SSRF was working at an energy of 3.5 GeV with an average electron current of 300 mA. The hard X-ray was monochromatized with a Si (311) monochromator. EXAFS data were collected in the transmission mode in the energy range from -200 below to 1000 eV above the Pt L₃-edge. The acquired EXAFS data were processed according to the standard procedures using the ARTEMIS module implemented in the IFEFFIT software packages.

2.9 X-ray crystallography

The data collection for single crystal X-ray diffraction was carried out on a Bruker Smart APEX II CCD diffractometer under liquid nitrogen flow at 200 K, using graphite-monochromatized Mo K α radiation ($\lambda = 0.71073 \text{ \AA}$). Data reductions and absorption corrections were performed using the SAINT and SADABS programs, respectively. The electron density was squeezed by Olex 2. The structure was solved by direct methods and refined with full-matrix least squares on F^2 using the SHELXTL software package. All non-hydrogen atoms were refined anisotropically, and all the hydrogen atoms were set in geometrically calculated positions and refined isotropically using a riding model.

3 Theoretical methods

Density functional theory (DFT) calculations were employed to optimize the geometric structures and calculate the Kohn–Sham orbitals of Pt₁Ag₂₈ nanoclusters using the Perdew–Burke–Ernzerhof (PBE) GGA functional.⁹ The triple-zeta polarized (TZP) basis set with inclusion of the scalar relativistic effect *via* a zeroth-order regular approximation (ZORA) implemented in the ADF package was adopted.¹⁰ In the electronic structure analysis, the Kohn–Sham orbitals were calculated to analyze contributions of different atomic orbital types to molecular orbitals.

3.1 Characterization

UV-vis absorption spectra of nanoclusters dissolved in CH₂Cl₂ were recorded using an Agilent 8453 diode array spectrometer.

Electrospray ionization time-of-flight mass spectrometry (ESI-TOF-MS) measurement was performed using a MicrOTOF-QIII high-resolution mass spectrometer.

PL spectra were measured on an FL-4500 spectrofluorometer with the same optical density (OD) of ~ 0.05 . Of note, the PL excitation spectrum of Pt₁Ag₂₈₋₁ or Pt₁Ag₂₈₋₂ was measured at 600 or 750 nm, respectively, for suppressing the interference from each other (*e.g.*, Pt₁Ag₂₈₋₁ fluoresces at 600 nm, while Pt₁Ag₂₈₋₂ does not fluoresce at this wavelength).

Quantum yields (QYs) were measured with dilute solutions of nanoclusters on a HORIBA FluoroMax-4P.

Transmission electron microscopy (TEM) was conducted on a JEM-2100 microscope with an accelerating voltage of 200 kV.

Thermogravimetric analysis (TGA) was carried out on a thermogravimetric analyser (DTG-60H, Shimadzu Instruments, Inc.)

X-ray photoelectron spectroscopy (XPS) measurement was performed on a Thermo ESCALAB 250, configured with a monochromated Al K α (1486.8 eV) 150 W X-ray source, 0.5 mm circular spot size, flood gun to counter charging effects, and analysis chamber base pressure lower than 1×10^{-9} mbar.

Inductively coupled plasma-atomic emission spectrometry (ICP-AES) measurements were performed on an Atomscan Advantage instrument made by Thermo Jarrell Ash Corporation.

Electrochemical measurements (differential pulse voltammetry, DPV) of clusters were performed with an electrochemical workstation (CHI 700E) using a Pt working electrode (0.4 mm diameter), a Pt wire counter electrode and an Ag wire quasi-reference electrode in 0.1 M Bu₄NPF₆-CH₂Cl₂. The electrolyte solution was deaerated with ultra-high purity nitrogen for 40 min and blanketed under a nitrogen atmosphere during the entire experimental procedure.

4 Results and discussion

4.1 Syntheses and crystallization

The Pt₁Ag₂₈₋₁ nanoclusters were prepared using our previously reported procedure.^{8b} The Pt₁Ag₂₈₋₂ nanoclusters were synthesized by reacting pure Pt₁Ag₂₈₋₁ with excess HS-c-C₆H₁₁ at 40 °C (see Experimental Methods for more details). After ~ 2 hours, all the Pt₁Ag₂₈₋₁ nanoclusters were completely converted into Pt₁Ag₂₈₋₂ in a high yield (>80%, Ag atom basis). The as-prepared Pt₁Ag₂₈₋₂ was crystallized by vapor diffusion of ether into a CH₂Cl₂ solution of the nanoclusters over 7 days. The Pt₁Ag₂₈₋₁ structure was reported by us in early work.^{8b} The structure of Pt₁Ag₂₈₋₂ is newly determined in the current work. X-ray photoelectron spectroscopy (XPS) and inductively coupled plasma (ICP) measurements were performed to validate the ratio of Pt/Ag in the bi-metallic Pt₁Ag₂₈₋₂ nanoclusters (Fig. S1, S2 and Table S1[†]), and the results perfectly matched the theoretical value (1/28 of Pt/Ag). Furthermore, the purity of Pt₁Ag₂₈₋₂ was confirmed by thermogravimetric analysis (TGA). The experimental weight loss of 49.57% (Fig. S3[†]) is consistent with the calculated loss (49.26%) of the ligands (*i.e.*, PPh₃ and S-c-C₆H₁₁) in Pt₁Ag₂₈₋₂. Both Pt₁Ag₂₈ nanoclusters are highly stable at 50 °C (Fig. S4[†]; clusters are dissolved in CHCl₃, and in contact with air). In the DPV analysis (Fig. S5[†]), Pt₁Ag₂₈₋₁ showed two oxidation peaks at 0.76 V (O1) and 1.28 V (O2) and a reduction peak at -1.32 V (R1); in comparison, Pt₁Ag₂₈₋₂ exhibited three oxidation peaks at 0.75 V (O1), 1.08 V (O2) and 1.45 V (O3) and a reduction peak at -0.92 V (R1). The catalytic performance of both Pt₁Ag₂₈ nanoclusters in the oxidation of styrene was evaluated (Fig. S6[†] and see the catalysis conditions in Experimental methods). The catalysis was performed at 50 °C to ensure that both clusters were stable. Although the catalytic selectivity for epoxide or benzaldehyde is similar in both catalysis, the overall catalytic conversion by Pt₁Ag₂₈₋₂@CNTs is much higher than that by Pt₁Ag₂₈₋₁@CNTs (66.48% *versus* 43.43%; shown in

Fig. S6†). Such a difference may result from the ligand effect between the two nanoclusters.

The $\text{Pt}_1\text{Ag}_{28}\text{-2}$ nanoclusters crystallize in the $P2_1/c$ space group. The structure of $\text{Pt}_1\text{Ag}_{28}\text{-2}$ is shown in Fig. 1A and the structural anatomy is shown in Fig. 1B–E (see Fig. S7† for the complete structure). Specifically, a single Pt atom is arranged in the innermost position of the overall structure (Fig. 1B), which is further capped by an Ag_{12} cage, forming a $\text{Pt}_1\text{Ag}_{12}$ kernel with an icosahedral configuration (Fig. 1C). Furthermore, this $\text{Pt}_1\text{Ag}_{12}$ kernel is surrounded by four $\text{Ag}_3(\text{S-c-C}_6\text{H}_{11})_6$ motifs. Of note, each $\text{Ag}_3(\text{S-c-C}_6\text{H}_{11})_6$ motif links with three other motifs *via* sharing the terminal thiolates, which constitutes a cage-like $\text{Ag}_{12}(\text{S-c-C}_6\text{H}_{11})_{18}$ motif structure fully surrounding the $\text{Pt}_1\text{Ag}_{12}$ kernel (Fig. 1D). Moreover, four Ag-PPh_3 architectures occupy the four vacancies of the aforementioned $\text{Pt}_1\text{Ag}_{12}@\text{Ag}_{12}(\text{S-c-C}_6\text{H}_{11})_{18}$ structure, giving rise to the final $\text{Pt}_1\text{Ag}_{28}\text{-2}$ structure. It should be noted that the capped $\text{Ag}_{12}(\text{SR})_{18}@\text{(Ag-PPh}_3)_4$

structure of $\text{Pt}_1\text{Ag}_{28}\text{-2}$ is similar to that of $\text{Pt}_1\text{Ag}_{28}\text{-1}$.^{8b} The TEM images of $\text{Pt}_1\text{Ag}_{28}\text{-1}$ and $\text{Pt}_1\text{Ag}_{28}\text{-2}$ indicate that the clusters are uniform in size of about 1.6 nm (Fig. S8†), and this agrees with that determined by X-ray structural analysis.

4.2 Reversible structure transformation

In order to elucidate the structural differences induced by the ligand exchange (*i.e.*, $\text{S-c-C}_6\text{H}_{11}$ versus S-Adm), a comparison of the kernels of $\text{Pt}_1\text{Ag}_{28}\text{-1}$ and $\text{Pt}_1\text{Ag}_{28}\text{-2}$ is provided in Fig. 2. Both $\text{Pt}_1\text{Ag}_{28}$ nanoclusters comprise a $\text{Pt}_1\text{Ag}_{12}$ kernel; however, the FCC configuration of the $\text{Pt}_1\text{Ag}_{12}$ kernel in $\text{Pt}_1\text{Ag}_{28}\text{-1}$ turns into the icosahedral configuration when the nanocluster converts to $\text{Pt}_1\text{Ag}_{28}\text{-2}$. The opposite process is also confirmed by reacting $\text{Pt}_1\text{Ag}_{28}\text{-2}$ with excess HS-Adm . Previously, two nanoclusters following the isomerism phenomenon are almost arranged in the same molecular configuration, *e.g.*, $\text{Au}_{21}(\text{S-Adm})_{15}$ and $\text{Au}_{21}(\text{S}^t\text{Bu})_{15}$ isomers with a FCC configuration,^{11,12} $\text{Au}_{28}(\text{S-Ph}^t\text{Bu})_{20}$ and $\text{Au}_{28}(\text{S-c-C}_6\text{H}_{11})_{20}$ isomers with a FCC configuration,^{6d,e} $\text{Au}_{52}(\text{S-Ph}^t\text{Bu})_{32}$ and $\text{Au}_{52}(\text{S-PhC}_2\text{H}_4)_{32}$ isomers with a FCC configuration,^{6c} $\text{Au}_9\text{Ag}_{12}(\text{S-Adm})_4(\text{dppm})_6\text{Cl}_6$ and $\text{Au}_9\text{Ag}_{12}(\text{S}^t\text{Bu})_4(\text{dppm})_6\text{Cl}_6$ with an icosahedral configuration,^{6f} and so on.

Fig. 1 $\text{Pt}_1\text{Ag}_{28}\text{-2}$ nanocluster and its structural anatomy. (A) Total structure. (B) Innermost Pt atom. (C) $\text{Pt}_1\text{Ag}_{12}$ kernel with an icosahedral configuration. (D) $\text{Pt}_1\text{Ag}_{12}$ kernel protected by four $\text{Ag}_3(\text{S-Adm})_6$ motifs. These four motifs make up a large $\text{Ag}_{12}(\text{S-Adm})_{18}$ motif wrapping the icosahedral kernel. (E) Four Ag-PPh_3 architectures occupy the vertex positions of the nanocluster. Color codes: green sphere, Pt; blue spheres, Ag; red spheres, S; purple spheres, P; and grey spheres, C. For clarity, the hydrogen atoms are not shown.

Fig. 2 Illustration of the reversible transformation between (A) the $\text{Pt}_1\text{Ag}_{28}\text{-1}$ nanocluster with a FCC $\text{Pt}_1\text{Ag}_{12}$ kernel and (B) the $\text{Pt}_1\text{Ag}_{28}\text{-2}$ nanocluster with an icosahedral $\text{Pt}_1\text{Ag}_{12}$ kernel induced by the addition of the $\text{HS-c-C}_6\text{H}_{11}$ or HS-Adm ligand. Insets: ESI-MS spectra of (C) $\text{Pt}_1\text{Ag}_{28}\text{-1}$ and (D) $\text{Pt}_1\text{Ag}_{28}\text{-2}$ nanoclusters. Insets: experimental and simulated isotope patterns of each nanocluster. Color codes: green sphere, Pt; blue spheres, Ag; red spheres, S; and purple spheres, P. For clarity, the carbon and hydrogen atoms are not shown.

Significantly, these two $\text{Pt}_1\text{Ag}_{28}$ isomers exhibit reversibility in terms of the kernel configuration between the FCC and icosahedron, which is observed for the first time in the nanocluster range (Fig. 2). Table 1 lists the comparison of bond lengths of Pt(core)–Ag(edge), Ag(edge)–Ag(edge), Ag(edge)–S(motif) and Ag(vertex)–P(vertex) between these two $\text{Pt}_1\text{Ag}_{28}$ isomers (see Fig. S9–S12† for the highlights of these types of bonds). Specifically, in $\text{Pt}_1\text{Ag}_{28-1}$, the bond lengths between the central Pt atom and the Ag atoms on the $\text{Pt}_1\text{Ag}_{12}$ shell range from 2.768 to 2.797 Å (average: 2.783 Å), whereas the Pt(core)–Ag(edge) distances in $\text{Pt}_1\text{Ag}_{28-2}$ shorten to 2.744–2.791 Å (average: 2.763 Å). In contrast, the average Ag(edge)–Ag(edge) bond length of 2.801 Å in $\text{Pt}_1\text{Ag}_{28-1}$ significantly increases to 2.915 Å (with a 4.07% difference) in $\text{Pt}_1\text{Ag}_{28-2}$. Furthermore, the average Ag(edge)–S bond length displays a 0.92% elongation in $\text{Pt}_1\text{Ag}_{28-2}$ compared with that of the $\text{Pt}_1\text{Ag}_{28-1}$ nanocluster. Moreover, the average Ag(vertex)–P bond length (2.400 Å) in $\text{Pt}_1\text{Ag}_{28-2}$ is also slightly longer than that in $\text{Pt}_1\text{Ag}_{28-1}$ (2.356 Å).

Electrospray ionization mass spectrometry (ESI-MS) was performed to verify the purity of each $\text{Pt}_1\text{Ag}_{28}$ isomer. As shown in Fig. 2C and D, the reaction between $\text{Pt}_1\text{Ag}_{28-1}$ and HS-*c*-C₆H₁₁ decreases the mass value from 3637.64 Da to 3169.36 Da, which is assigned to $\text{Pt}_1\text{Ag}_{28-2}$. The magnification of the peak suggests a +2 charge state of $\text{Pt}_1\text{Ag}_{28-2}$, since this peak evidences a characteristic isotopic pattern with peaks separated by an *m/z* of 0.5 Da (in the positive mode). In this context, the overall charge state of these two $\text{Pt}_1\text{Ag}_{28}$ isomers is the same +2. Of note, the +2 charge state of $\text{Pt}_1\text{Ag}_{28-2}$ matches the crystal data, because two negative (BPh₄)[−] counterions were observed in the crystal structure of $\text{Pt}_1\text{Ag}_{28-2}$. In addition, the gap between the mass peaks of two $\text{Pt}_1\text{Ag}_{28}$ isomers is calculated as 936.56 Da (*i.e.*, (3637.64 – 3169.36) × 2), which is in accordance with 18-fold the molecular weight gap between HS-Adm and HS-*c*-C₆H₁₁ ligands.

It is accepted that the structures of nanoclusters play a decisive role in their chemical/physical properties.^{1a,b,f,h} The optical properties of $\text{Pt}_1\text{Ag}_{28}$ isomers are compared here to investigate the precise structure–property correlation. First of all, the time-dependent variation of UV-vis absorption from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$ was recorded. As shown in Fig. 3A, the absorptions at 545 and 443 nm in $\text{Pt}_1\text{Ag}_{28-1}$ red-shift to 575 and 455 nm, respectively, in $\text{Pt}_1\text{Ag}_{28-2}$. Furthermore, the 333 and 305 nm absorption peaks in $\text{Pt}_1\text{Ag}_{28-1}$ become more pronounced and red-shift to 350 and 315 nm, respectively. A total of four iso-absorption points are observed, centering at

307, 338, 427 and 454 nm. These iso-absorption points illustrate the high level of conversion from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$. The solution of $\text{Pt}_1\text{Ag}_{28-2}$ appears green to the naked eye, while the $\text{Pt}_1\text{Ag}_{28-1}$ solution is orange (Fig. 3A, insets). The photon energy plots of the two $\text{Pt}_1\text{Ag}_{28}$ isomers were recorded (Fig. 3B), which demonstrate that the energy gap (between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO)) of $\text{Pt}_1\text{Ag}_{28-2}$ (1.74 eV) is much smaller than that of $\text{Pt}_1\text{Ag}_{28-1}$ (1.86 eV); this is possibly due to the configuration transformation from the FCC to the icosahedron. In addition, accompanied by the ligand-exchange process from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$, gradual reduction was detected in the HOMO–LUMO gap (Fig. 3B).

Fig. 3C and D show the PL performances of the $\text{Pt}_1\text{Ag}_{28}$ isomers. First of all, the PL excitation spectra are almost identical to the absorption spectra, which is reminiscent of the behavior of quantum-dots and some nanoclusters.^{8b,13} In addition, the emission peak wavelength is not dependent on the excitation wavelength but remains at 672 nm for $\text{Pt}_1\text{Ag}_{28-1}$ and at 720 nm for $\text{Pt}_1\text{Ag}_{28-2}$. Furthermore, the emission of each isomer (*i.e.*, 1.84 eV of $\text{Pt}_1\text{Ag}_{28-1}$ and 1.72 eV of $\text{Pt}_1\text{Ag}_{28-2}$) is very close to the HOMO–LUMO gap energy derived from the optical absorption spectrum. The extremely small difference in energy illustrates that the fluorescence corresponds to the HOMO–LUMO transition of each $\text{Pt}_1\text{Ag}_{28}$ isomer.

The structures of nanoclusters are determinant of their physical and chemical properties.^{1a,b,f,h} In this context, the significant red-shift of the emission wavelength from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$ (~50 nm) is traceable to the kernel transformation from the FCC to icosahedron. Considering that the kernel transformation is induced by the ligand exchange, we were motivated to track this configuration variation by matching the ESI-MS changes and the corresponding emission variations. Here, the ESI-MS and fluorescence variations from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$ are detected since the corresponding transformation is much slower than the reverse process, and thus is easier to monitor (see Fig. S13–S15† for the UV-vis, ESI-MS and PL variations from $\text{Pt}_1\text{Ag}_{28-2}$ to $\text{Pt}_1\text{Ag}_{28-1}$). First of all, ESI-MS measurements were performed to monitor the ligand-exchange degree of each stage from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$ (Fig. 3E), and the time-dependent ligand-exchange process in mild and stepwise modes was deduced. Furthermore, the fluorescence variation can be divided into two periods (Fig. 3F, see the lateral comparison in Fig. S16†): (Period 1) from stage 1 to stage 5: each fluorescence curve only exhibits a single characteristic peak, although the emission red-shifts from 672 nm of stage 1 to 674, 675, 677, and 678 nm of stages 2–5, respectively; (Period 2) from stage 6 to stage 9: each emission curve contains two overlapping peaks, where the front peak decreases accompanying the ligand-exchange process, but the rear one increases gradually. Finally, the fluorescence curve just exhibits a single peak at 720 nm, which is the emission of pure $\text{Pt}_1\text{Ag}_{28-2}$ (stage 9). Combining the variations of ESI-MS and fluorescence, the emission just displays a slight red-shift when the number of ligands exchanged on $\text{Pt}_1\text{Ag}_{28-1}$ is less than 9–10 (stages 1–5, depicted by the blue arrow in Fig. 3F). When exchanging more ligands onto the nanocluster, a new peak emerges at 712 nm

Table 1 Comparison of different bond lengths in $\text{Pt}_1\text{Ag}_{28-1}$ and $\text{Pt}_1\text{Ag}_{28-2}$ crystal structures

Bond length (Å)	$\text{Pt}_1\text{Ag}_{28-1}$	$\text{Pt}_1\text{Ag}_{28-2}$	Diff.
Pt(core)–Ag(edge)	2.768–2.797 Avg. 2.783	2.744–2.791 Avg. 2.763	0.72%
Ag(edge)–Ag(edge)	2.761–2.843 Avg. 2.801	2.819–3.309 Avg. 2.915	4.07%
Ag(edge)–S	2.438–2.498 Avg. 2.472	2.480–2.517 Avg. 2.495	0.92%
Ag(vertex)–P	2.292–2.384 Avg. 2.356	2.395–2.409 Avg. 2.400	1.87%

Fig. 3 Real-time alternation of the (A) UV-vis absorption and (B) photon-energy plot from $\text{Pt}_1\text{Ag}_{28-1}$ (in black) to $\text{Pt}_1\text{Ag}_{28-2}$ (in red). Four isoabsorption points are observed at 307, 338, 427 and 454 nm, as depicted in (A). Insets of (A): photographs of the nanocluster solutions. Excitation spectrum (left) and emission spectra (right) of (C) $\text{Pt}_1\text{Ag}_{28-1}$ and (D) $\text{Pt}_1\text{Ag}_{28-2}$ at different excitation wavelengths, as indicated by the arrows. Time-dependent (E) ESI-MS spectra and (F) PL emission spectra from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$. Insets of (F): dotted curves represent the separated overlapped curves. The blue arrow indicates the red-shift and reduction of the emission at ~ 672 nm. The red arrow indicates the red-shift and enhancement of the emission at ~ 720 nm.

(stage 6). This new peak gradually red-shifts and increases to the final emission at 720 nm (stages 6–9, depicted by the red arrow in Fig. 3F), in which process the peak at ~ 672 nm fades away. According to these phenomena, we propose that the transformation from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$ is a two-step process (Fig. 4): (i) the motif transformation process: the outmost motif structures alter gradually when inadequate $\text{S-c-C}_6\text{H}_{11}$ ligands are exchanged on the surface of the $\text{Pt}_1\text{Ag}_{28}$ nanocluster. In this process the FCC configuration of the $\text{Pt}_1\text{Ag}_{12}$ kernel remains (corresponding to stages 1–5); (ii) the kernel transformation process: sharp transformation of the kernel configuration from the FCC to icosahedron occurs as long as enough foreign ligands have been exchanged on the nanocluster surface, and finally all $\text{Pt}_1\text{Ag}_{28}$ nanoclusters contain the icosahedral $\text{Pt}_1\text{Ag}_{12}$ kernel (corresponding to stages 6–9). In addition, considering that the exchanged ligands do not come into contact with the innermost $\text{Pt}_1\text{Ag}_{12}$ kernel directly, we speculate that the kernel transformation occurs as a result of the motif transformation.

4.3 XAFS measurements

Our repeated attempts to crystallize the samples from stages 2–8 were unsuccessful, which might be because such $\text{Pt}_1\text{Ag}_{28}$ samples

are protected by different proportions of S-Adm and $\text{S-c-C}_6\text{H}_{11}$ ligands (Fig. 3E, stages 2–8). XAFS measurements were performed for grasping the structural variation of $\text{Pt}_1\text{Ag}_{28}$ nanoclusters in different stages. XAFS results of stages 1, 3, 5, 7, and 9 are recorded since such results are capable of revealing the structural variations that correspond to the initial PL red-shift (672 nm \rightarrow 678 nm) and the further abrupt changes (678 nm \rightarrow 712 nm). As shown in Fig. 5 and Table 2 (see Fig. S17–S21† for more information), the fitted number of Pt–Ag bonds in each $\text{Pt}_1\text{Ag}_{28}$ sample is 12, which is in accordance with the $\text{Pt}_1\text{Ag}_{12}$ kernel in both FCC- $\text{Pt}_1\text{Ag}_{28}$ and icosahedral- $\text{Pt}_1\text{Ag}_{28}$ nanoclusters. Furthermore, the invariable bond lengths of Pt–Ag (remaining as 2.75 ± 0.01 Å, Table 2) in these samples validate the extremely small difference (cal. 0.72%, Table 1) in average Pt(core)–Ag(edge) bond lengths in $\text{Pt}_1\text{Ag}_{28-1}$ and $\text{Pt}_1\text{Ag}_{28-2}$.

Importantly, both the $k^2\chi(k)$ oscillation and Fourier transform curves of stages 1–5 demonstrate that the Pt–Ag bonds are almost invariable in these stages (Fig. 5 and Table 2); however, the lower intensity of the Fourier transformed EXAFS $k^2\chi(k)$ oscillations in stages 1–5 than in stages 7–9 indeed shows the higher disorder degree of Pt–Ag bonds in the former, *i.e.*, the

Fig. 4 Proposed two-step transformation from $\text{Pt}_1\text{Ag}_{28-1}$ to $\text{Pt}_1\text{Ag}_{28-2}$.

Fig. 5 (A) $k^2\chi(k)$ oscillations of Pt L_3 and (B) corresponding Fourier transforms for $\text{Pt}_1\text{Ag}_{28}$ samples at different stages.

Table 2 Fitted EXAFS results of Pt₁Ag₂₈ samples corresponding to stages 1, 3, 5, 7, and 9 that relate to Fig. 3

Stage	Path	N	R (Å)	σ^2 (10^{-3} Å ²)	ΔE_0 (eV)
1	Pt–Ag	12	2.75 ± 0.01	6.9 ± 0.2	5.5 ± 0.6
3	Pt–Ag	12	2.75 ± 0.01	7.1 ± 0.2	5.3 ± 0.4
5	Pt–Ag	12	2.75 ± 0.01	7.0 ± 0.1	5.5 ± 0.4
7	Pt–Ag	12	2.75 ± 0.01	6.3 ± 0.3	5.7 ± 0.9
9	Pt–Ag	12	2.75 ± 0.01	6.3 ± 0.2	5.7 ± 0.7

larger Debye–Waller factor σ^2 listed in Table 2. Generally, the Debye–Waller factor σ^2 is a sum of two components, thermal disorder (σ_T^2) and structural disorder (σ_S^2), i.e., $\sigma^2 = \sigma_T^2 + \sigma_S^2$. From the single crystal XRD analysis (Table 1), the Pt–Ag bond lengths in Pt₁Ag₂₈-1 span a narrower range of 0.029 Å (from 2.768 to 2.797 Å, average 2.783 Å) than that (0.047 Å, varying from 2.744 to 2.791 Å, average 2.763 Å) in Pt₁Ag₂₈-2, indicating a smaller structural disorder σ_S^2 in the FCC isomer. The larger σ^2 but smaller σ_S^2 of the Pt–Ag bonds in Pt₁Ag₂₈-1 than in icosahedral Pt₁Ag₂₈-2 suggests that the thermal disorder σ_T^2 is larger in Pt₁Ag₂₈-1. It is known that when the measurement temperature T is close to or higher than the Einstein temperature of a bond, the thermal disorder σ_T^2 could be approximated by the correlated Einstein model: $\sigma_T^2 = k_B T / k_{\text{eff}}$, where k_B is the Einstein temperature and k_{eff} is the effective spring constant of the bond.¹⁴ Therefore, the larger thermal disorder σ_T^2 in Pt₁Ag₂₈-1 indicates that the Pt–Ag interaction (reflected by the effective spring constant) is weaker in Pt₁Ag₂₈-1 than in Pt₁Ag₂₈-2, or the Pt–Ag bond is strengthened in Pt₁Ag₂₈-2. This deduction is supported by the fact that, from the XRD analysis, the average Pt–Ag bond length (2.783 Å) in Pt₁Ag₂₈-1 is longer by 0.02 Å than that (2.763 Å) in Pt₁Ag₂₈-2. More support could also be afforded by the Kohn–Sham molecular orbitals (MO) of both clusters yielded by DFT calculations (Fig. S22†). The bonding HOMO orbitals of Pt₁Ag₂₈-1 are composed of 2.16% Pt 6sp, 2.29% Pt 5d, 26.03% Ag 5sp, 20.3% Ag 4d, and 41.67% S 3p orbitals, while the HOMO orbitals of Pt₁Ag₂₈-2 are composed of 4.08% Pt 6sp, 1.24% Pt 5d, 39.79% Ag 5sp, 21.46% Ag 4d, and 26.97% S 3p orbitals. The smaller amount of Pt orbital components in Pt₁Ag₂₈-1 than in Pt₁Ag₂₈-2 (4.45% versus 5.22%) suggests the weaker Pt–Ag bonding in the former. This is also consistent with the consideration based on antibonding LUMO orbitals, where Pt₁Ag₂₈-1 has a larger amount of Pt orbital components than Pt₁Ag₂₈-2 (8.04% versus 7.33%).

EXAFS results indeed illustrate that the kernel transformation occurs within the ligand-exchange process from stage 5 to stage 7. Such a process (stage 5 → stage 7) is also regarded as the break point where significant PL variation occurs (Fig. 3F). In this context, by combining the ESI-MS, PL and EXAFS variation results, it has been unambiguously demonstrated that the nanocluster configuration transformation (from FCC to icosahedron) contains two discrete steps: the motif transformation and the kernel transformation. Specifically, in the early stage of the ligand-exchange process (stages 1–5), only the motif transformation occurs, which hardly affects the inner Pt–Ag bonds; when enough foreign ligands are

exchanged on the Pt₁Ag₂₈ nanocluster (stages 5–9), remarkable transformation in the kernel occurs and the FCC configuration turns into the icosahedral configuration.

4.4 Temperature-dependent PL

The PL QY of Pt₁Ag₂₈-2 is only 2.7% at room temperature, which is much lower than that of Pt₁Ag₂₈-1 (QY ~ 4.9%). However, Pt₁Ag₂₈-2 can emit bright-red light at low temperature (QY ~ 100% at 98 K or lower temperature). Accordingly, the fluorescence intensity increased significantly (a 63-fold increase by comparing the 98 K data with the 293 K data) when the temperature is reduced to 98 K (Fig. 6A–C), and the UV-vis absorption presents a 1.8-fold enhancement (Fig. 6D). In this context, the PL QY of Pt₁Ag₂₈-2 increases to almost 100%. In detail, when the temperature is higher than 250 K, the PL intensity is so weak that it cannot be observed by the naked eye (Fig. 6B, inset 275 K). When the temperature is continually reduced, the PL intensity enhances rapidly, and an obvious emission can be observed at 173 K (Fig. 6B, inset 173 K). Furthermore, the emission of Pt₁Ag₂₈-2 nanoclusters is considerably bright when the temperature is reduced to 98 K or lower (Fig. 6B, inset 98 K). The enhanced PL intensity of Pt₁Ag₂₈-2 is induced by the restrained thermal vibration (non-radiative

Fig. 6 (A) PL variation of Pt₁Ag₂₈-2 accompanying the reduction of temperature (from 293 K to 77 K, monitored per 3 K). (B) PL intensity at a fixed wavelength of 720 nm of Pt₁Ag₂₈-2 at different temperatures. Insets: the digital photographs of Pt₁Ag₂₈-2 solution under UV light. (C) Derivative result on the PL intensity of Pt₁Ag₂₈-2. (D) Temperature-dependent UV-vis absorption of Pt₁Ag₂₈-2. (E) PL variation of the intermediate ligand-exchange product (stage 7) accompanying the reduction of temperature. (F) Fitted curves of the PL spectrum of the intermediate ligand-exchange product (stage 7) measured at 77 K.

transition) of the nanoclusters at low temperature, and thus the energy loss is just fluorescence (radiative transition).¹⁵ For comparison, the PL variation of **Pt₁Ag₂₈-1** accompanying the reduction of the temperature is exhibited in Fig. S23.†

Temperature-dependent PL spectra were also measured on the intermediate ligand-exchange Pt₁Ag₂₈ product. Specifically, we chose the product of stage 7 (see Fig. 3E and F) because the PL spectrum of this product displays the most obvious overlapping peaks. As shown in Fig. 6E, accompanying the reduction of temperature from 293 K to 77 K, the overlapped peaks become sharper and more separated. Meanwhile, the emission intensity appears to be significantly enhanced in the temperature reduction process. In this context, the peak-fitting becomes more easy and precise. Fig. 6F exhibits the overlapped curves from the PL spectrum of the intermediate ligand-exchange product (stage 7) measured at 77 K. Two independent curves were separated from the multi-peak PL spectrum, and they center at 680 and 713 nm, respectively. Of note, the fitting-peak positions are retained for these two separated curves; however, following the temperature reduction, the relative intensity of the fitted curve at ~680 nm becomes stronger relative to the other one, which demonstrates the different emission performance of the FCC-Pt₁Ag₂₈ and icosahedral-Pt₁Ag₂₈ nanoclusters with the temperature reduction.

5 Conclusions

In summary, a ligand-exchange method was exploited to reversibly transform the **Pt₁Ag₂₈-1** nanoclusters with a FCC configuration and the **Pt₁Ag₂₈-2** nanoclusters with an icosahedral configuration. This is the first time that the isomerism phenomenon with reversible configurations has been observed. ESI-MS, PL and EXAFS results were combined to illustrate that the configuration transformation (between FCC and icosahedron) is a two-step process, including the outmost motif transformation process and the innermost kernel transformation process, where the latter transformation is induced by the former one. Based on these Pt₁Ag₂₈ isomers, the corresponding structure–optical property correlation was evaluated. UV-vis absorption, together with PL emission, demonstrates a reduced HOMO–LUMO gap of **Pt₁Ag₂₈-2** compared with that of **Pt₁Ag₂₈-1**. Overall, this work presents a nanocluster isomer system with a reversibly transforming configuration, which hopefully draws great attention of structural and theoretical chemists to fully understand the structural transformations as well as the structure–property correlation of metal nanoclusters.
