Phlomideae

Taxonomy

ABSTRACT

Phlomoides, with 150–170 species, is the second largest and perhaps most taxonomically challenging genus within the subfamily Lamioideae (Lamiaceae). With about 60 species, China is one of three major biodiversity centers of *Phlomoides*. Although some *Phlomoides* species from China have been included in previous molecular phylogenetic studies, a robust and broad phylogeny of this lineage has yet to be completed. Moreover, given the myriad new additions to the genus, the existing infrageneric classification needs to be evaluated and revised. Here, we combine molecular and morphological data to investigate relationships within *Phlomoides*, with a focus on Chinese species. We observed that plastid DNA sequences can resolve relationships within *Phlomoides* better than nuclear ribosomal internal and external transcribed spacer regions (nrITS and nrETS). Molecular phylogenetic analyses confirm the monophyly of *Phlomoides*, but most previously defined infrageneric groups are not monophyletic. In addition, morphological analysis demonstrates the significant taxonomic value of eight characters to the genus. Based on our molecular phylogenetic analyses and morphological data, we establish a novel section *Notochaete* within *Phlomoides*, and propose three new combinations as well as three new synonyms. This study presents the first molecular phylogenetic analyses of *Phlomoides* in which taxa representative of the entire genus are included, and highlights the phylogenetic and taxonomic value of several morphological characters from species of *Phlomoides* from China. Our study suggests that a taxonomic revision and reclassification for the entire genus is necessary in the future.

1. Introduction

The Lamiaceae Martinov, commonly known as mints, have long served as a model system for evolutionary studies due to their morphological/biogeographical diversity and complexity (Bentham,

1832–1836; Cantino, 1992; Hedge, 1992; Harley et al., 2004; Mint Evolutionary Genomics Consortium, 2018; Rose et al., 2022). Lamiaceae are the sixth most species-rich family of angiosperms, with about 230 genera and 7000 species (Harley et al., 2004; Zhao et al., 2021a). The distribution of the family is virtually worldwide, but seven diversity centers are recognized: (1) The Mediterranean region and Southwest Asia, (2) Sub-Saharan Africa including Madagascar, (3) China, (4) Australia, (5) South America, (6) the southwest United States and Mexico, (7) and Southeast Asia (Hedge, 1992; Harley et al., 2004; Rose et al., 2022).

As one of the seven diversity centers of Lamiaceae, China contains at least 96 genera and 970 species (Xiang et al., 2017), of which seven genera (i.e., *Hanceola* Kudô, *Heterolamium* C.Y. Wu, *Holocheila* (Kudô) S. Chow, *Loxocalyx* Hemsl., *Ombrocharis* Hand.-Mazz., *Rostrinucula* Kudô, and *Schnabelia* Hand.-Mazz.) are endemic to China (Wu and Li, 1977; Li and Hedge, 1994). In addition, China is considered a diversity hotspot for several widespread genera such as *Dracocephalum* L., *Elsholtzia* Willd., *Isodon* (Schrad. ex Benth.) Spach, *Nepeta* L., *Phlomis* Moench, *Salvia* L., and *Scutellaria* L. (Paton, 1990; Walker and Sytsma, 2007; Salmaki et al., 2012a; Hu et al., 2018, 2020; Zhao et al., 2017, 2021a,b,c, 2022; Chen et al., 2022a; Sun et al., 2022). During the past two decades, the circumscription of Lamiaceae and evolutionary relationships within the family have been gradually clarified based on a series of molecular phylogenetic studies (Scheen et al., 2010; Bendiksby et al., 2011; Drew and Sytsma, 2012; Li et al., 2016; Drew et al., 2017; Li and Olmstead, 2017; Zhao et al., 2021a). Concurrently, the phylogenetic position of several rare or endemic Chinese genera has been illuminated (Li et al., 2012; Xiang et al., 2013, 2018; Chen et al., 2014, 2016; Li et al., 2017a; Zhao et al., 2021d). To date, the species diversity and phylogenetic relationships of most large mint genera within China have been well documented (Yu et al., 2014; Yao et al., 2016; Li et al., 2017b; Hu et al., 2018, 2020; Zhao et al., 2017, 2020; Chen et al., 2021, 2022a,b), with only two large genera, *Nepeta* (42 spp. in China) (Wu and Li, 1977; Li and Hedge, 1994) and *Phlomis* (58 spp. in China) (Li, 1985; Li and Hedge, 1994; Xiang et al., 2014; Zhao et al., 2021b,c, 2022, 2023a), lacking a comprehensive molecular phylogenetic treatment.

Phlomis was established by Moench (1794), but it has generally been treated as a section of *Phlomis* L. Although *Phlomis* was resurrected as a genus based on corolla shape and fruit structure (Adylov et al., 1986; Adylov, 1987; Kamelin and Machmedov, 1990a,b), the genus was not widely accepted (Ryding, 2008) until Scheen et al. (2010) confirmed it as a separate genus using molecular data. The separation of *Phlomis* from *Phlomis* was later affirmed by studies with broader taxon sampling (Bendiksby et al., 2011; Salmaki et al., 2012a). Subsequent molecular phylogenetic studies demonstrated that at least seven genera should be transferred to *Phlomis* (Scheen et al., 2010; Bendiksby et al., 2011; Mathiesen et al., 2011; Salmaki et al., 2012a; Zhao et al., 2023a,b), including *Eremostachys* Bunge, *Lamiophlomis* Kudô, *Metastachydium* Airy Shaw ex C.Y. Wu & H.W. Li, *Notochaete* Benth., *Paraeremostachys* Adylov et al., *Pseuderemostachys* Popov, and *Pseudomarrubium* Popov, making the redefined *Phlomis* one of the largest and most heterogeneous genera of Lamiaceae, with ca. 150–170 spp. (Salmaki et al., 2012a,b; Zhao et al., 2021b,c, 2022, 2023a,b).

As currently defined, *Phlomis* is mainly distributed in mountain steppe and (semi-) desert areas of three regions: Central Asia, the Iranian highlands, and China (Czerepanov, 1995; Salmaki et al., 2012b; Xiang et al., 2014; Zhao et al., 2022). In total, 58 species and 17 varieties can be found in China (Li, 1985; Li and Hedge, 1994; Xiang et al., 2014; Zhao et al., 2021b,c, 2022, 2023a), with 37 species and 9 varieties occurring in the Hengduan Mountains (HM) and Qinghai-Tibet Plateau region (QTP).

Phlomis are quite variable in leaf, bract, calyx, and corolla morphology, as well as in habitat (Fig. 1). *Phlomis* differs from its sister group, *Phlomis*, by the following set of characters: generally perennial herbs (vs. small shrubs or occasionally perennial herbs), cordate to triangular-ovate leaves, simple or lacinate to bipinnatisect (vs. lanceolate to oblong-lanceolate, not deeply lobed), upper corolla lips that are dome-shaped with hairy or fringed-incised apices (vs. laterally compressed, flattened, sickle-shaped, apices not fringed-incised), and a basic chromosome number of $x = 11$ (vs. $x = 10$) (Azizian and Cutler, 1982; Astanova, 1984; Ghaffari, 2006; Fang et al., 2007; Mathiesen et al., 2011; Salmaki et al., 2012a). The genus is widely regarded as taxonomically challenging due to some common characters shared among species, and because of considerable morphological variation in characters used to differentiate species. Currently, there is no definitive infrageneric classification and our knowledge of species delimitations within the genus is largely based on regional taxonomic work (e.g., Popov, 1926, 1940; Knorrning, 1954; Hsuan, 1977; Rechinger, 1980; Li and Hedge, 1994; Sennikov and Lazkov, 2013; Lazkov and Sennikov, 2015; Ranjbar and Mahmoudi, 2015, 2017).

In China, *Flora Reipublicae Popularis Sinicae* (Wu and Li, 1977) and *Flora of China* (Li and Hedge, 1994) are the two most important references for Lamiaceae taxonomy. However, at the time of those works, most *Phlomis* as currently understood were treated as a section within *Phlomis* [i.e., *Phlomis* sect. *Phlomis* (Moench) Briq.] while others were treated as separate genera (i.e., *Lamiophlomis*, *Eremostachys*, *Metastachydium*, and *Notochaete*). In addition, the most complete infrageneric classification system for Chinese *Phlomis* was developed using only external morphology (Hsuan, 1977), and is not comprehensive in terms of taxon treatment. Based on leaf, trichome, calyx and stamen morphology, Hsuan (1977) divided Chinese *Phlomis* into two subsections and 17 series (seven monotypic). This classification, however, tends to be ambiguous due to the substantial variation in morphological characters among the treated taxa. Furthermore, phylogenetic studies have substantially changed the concept of the genus (Scheen et al., 2010; Bendiksby et al., 2011; Salmaki et al., 2012a; Zhao et al., 2023a,b), with a much broader interpretation of *Phlomis* now accepted. Thus, the current classification system is sorely outdated and a revised classification scheme for *Phlomis* is necessary.

DNA-based phylogenetic analyses provide an effective complement to morphology in approaching taxonomic challenges. Taxonomic problems in several genera of Lamiaceae have been resolved with the support of molecular analyses using plastid DNA regions (e.g., *atpB-rbcL*, *psbA-trnH*, *rpl16*, *rpl32-trnL*, *rps16*, *trnK*, *trnL-trnF*, *trnS-trnG*, *trnT-trnL*, *ycf1*) and nuclear ribosomal nrITS and nrETS regions (Paton et al., 2004; Walker et al., 2004; Bräuchler et al., 2010; Drew and Sytsma, 2011, 2012; Pastore et al., 2011; Wilson et al., 2012; Xiang et al., 2013, 2018; Li et al., 2016; Yao et al., 2016; Hu et al., 2018; Chen et al., 2021). However, our current phylogenetic understanding of *Phlomis* is limited, with only a few studies including representatives from this genus (Fang et al., 2007; Scheen et al., 2010; Bendiksby et al., 2011; Mathiesen et al., 2011; Salmaki et al., 2012a; Zhao et al., 2023a), and genetic data are only available for a few species of *Phlomis* native to China. The lack of a detailed molecular phylogenetic framework of the genus leaves a gap in understanding species relationships as well as the evolutionary history of the genus. As one of the three diversity centers of *Phlomis*, a molecular study focusing on taxa native to China is an important first step in elucidating the broader *Phlomis* taxonomy.

Here, we use nine chloroplast markers (*atpB-rbcL*, *psbA-trnH*, *rpl16*, *rpl32-trnL*, *rps16*, *trnK*, *trnL-trnF*, *trnS-trnG*, *trnT-trnL*) and two nuclear DNA regions—nrETS and nrITS—to reconstruct the

phylogeny of Chinese *Phlomoides* species. The infrageneric classification system proposed by Hsuan (1977) is compared with molecular results. Integrating molecular and morphological evidence, we aim to evaluate and revise the infrageneric classification of

Chinese *Phlomoides*. The objectives of this study are to (1) present a comprehensive phylogenetic reconstruction of *Phlomoides*, with an emphasis on the Chinese taxa; (2) provide a phylogenetic background to test the infrageneric classification of Hsuan (1977) and

revise the classification; (3) further contribute to a comprehensive phylogenetic framework for subfamily Lamioideae.

2. Materials and methods

2.1. Plant materials

The ingroup included 111 samples representing 85 species and 6 varieties of *Phlomis* and four individuals representing three *Phlomis* taxa (*Phlomis herba-venti* L. subsp. *pungens* (Willd.) Maire ex DeFilippis, *P. fruticosa* L., *P. composita* Pau), of which 51 species and 6 varieties (about 88% of total taxa) are distributed in China. Fresh leaves were collected and dried with silica gel, and voucher specimens were deposited in the Kunming Institute of Botany, Chinese Academy of Sciences. Materials of 34 individuals representing 31 species were sampled from herbarium specimens held at K, LE, and MW (Table S1). Two species each from tribes Lamieae (*Lamium amplexicaule* L. and *L. album* L.), Leucadeae (*Leonotis leonurus* (L.) R.Br. and *Leucas mollissima* Wall. ex Benth.), Leonureae (*Leonurus cardiaca* L. and *L. japonicus* Maxim.), Marrubieae (*Marrubium vulgare* L. and *Pseudodictamnus mediterraneus* Salmaki & Siadati) and three species of Paraphlomideae (*Paraphlomis albida* Hand.-Mazz., *P. hispida* C.Y. Wu and *P. nana* Y.P. Chen, C. Xiong & C.L. Xiang) were selected as an outgroup based on previous findings (Salmaki et al., 2012a; Zhao et al., 2021a).

Our taxon sampling was broad, encompassing the geographic range of the genus, including East Asia (most parts of China including the QTP and HM regions, Bhutan, Mongolia; 47 species), Central Asia (Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, Uzbekistan; 28 species), Southwest Asia (Afghanistan, Armenia, Iran; 9 species) and Europe (Ukraine, 1 species). This broad sampling offers the opportunity to reconstruct the backbone of the *Phlomis* phylogeny and identify major lineages within the genus.

2.2. DNA extraction, amplification, and sequencing

Total genomic DNA was extracted either from silica-gel-dried leaf material using the modified CTAB method (Doyle and Doyle, 1987) or from herbarium specimens following Zeng et al. (2018). In this study, nine chloroplast DNA (cpDNA) markers (*atpB-rbcL*, *psbA-trnH*, *rpl16*, *rpl32-trnL*, *rps16*, *trnK*, *trnL-trnF*, *trnS-trnG*, *trnT-L*) and two nuclear DNA regions—nrITS and nrETS—were selected for phylogenetic reconstruction. Primers, mixtures and procedures for *atpB-rbcL*, *psbA-trnH*, and *trnT-trnL* followed Albaladejo et al. (2005), *trnK* and *rpl32-trnL* followed Salmaki et al. (2012a), *trnS-trnG* followed Scheen and Albert (2009), while *rpl16*, *rps16*, and *trnL-trnF* followed Chen et al. (2021). The primer pairs ETS-B (Beardsley and Olmstead, 2002) and 18S-IGS (Baldwin and Markos, 1998) were used for the amplification of nrETS, and Leu1 (Vargas et al., 1998) and ITS4 (White et al., 1990) for nrITS. PCR and sequencing protocols for two nrDNA markers followed Xiang et al. (2013).

Sequencing reactions were performed with the dideoxy chain termination method running on an ABI PRISM 3730 automated sequencer. All sequences used in this study together with their GenBank accession numbers are listed in Table S2.

2.3. Sequence alignment and phylogenetic analyses

Raw sequences were assembled and edited using Geneious v.11.0.3 (Kearse et al., 2012) and aligned by the MAFFT v.7.308 (Katoh and Standley, 2013) with the G-INS-I algorithm. The final alignments were adjusted manually in PhyDE v.0.9971 (Müller et al., 2010). Three different datasets were analyzed: the cpDNA

and nrDNA alignments separately, and an analysis with all data combined.

All datasets were analyzed using Bayesian inference (BI) and maximum likelihood (ML). The best-fit substitution model for each data set was selected by the jModelTest v.3.7 (Posada, 2008) under the Akaike information criterion (AIC) score. BI and ML analyses were conducted on the Cyberinfrastructure for Phylogenetic Research Science (CIPRES) Science Gateway v.3.3 (Miller et al., 2010), using MrBayes (Ronquist et al., 2012) and RAxML v.8.2.9 (Stamatakis, 2014), respectively. Details for parameter settings followed Zhao et al. (2023b). All phylogenetic trees with posterior probabilities (PP) and bootstrap values (BS) were exhibited and annotated in FigTree v.1.4.2 (Rambaut, 2014). The R package Phytools v.2.1.1 (Revell, 2012) was used to compare topological incongruence between the cpDNA and nrDNA trees.

2.4. Morphological data

To test the taxonomic value of morphological characters (habit, basal leaves, calyces, bracts, corolla, and nutlets) traditionally used for the classification of Chinese species of *Phlomis*, we carefully investigated those characters in the field and with herbarium specimens. We recorded the habit, the shapes of basal and stem leaves, and dissected corolla tubes. All images were taken by a digital single-lens-reflex camera, and a ruler was used during photography. Finally, we summarized these characters for each investigated species. Eight morphological characteristics were selected and mapped onto the tree to infer trait evolution within *Phlomis*, including three vegetative characteristics [habit (herb/shrub), basal leaves (absent/present), and division of leaves (simple/laciniate)], four floral characteristics [calyx shape (tubular/campanulate or infundibular), bract shape (straight/hooks), upper corolla lip shape (galeate/erect) and upper corolla beard color (white/brown to black)] and one fruit trait [nutlet apex (dense simple long trichomes/glabrous or with sparse branched trichomes)].

3. Results

3.1. Sequences and alignment characterization

For this study, 570 sequences were newly generated (Table S2). The cpDNA and nrDNA datasets used in this study were deposited in Figshare (10.6084/m9.figshare.23936628). The combined nrDNA dataset consisted of 124 individuals and 1253 aligned nucleotide position characters (695 nucleotides were variable), of which 703 positions were from the ITS1-5.8S-ITS2 region, while the nrETS region contributed 550 bp. Sequence lengths were 2317–2360 nucleotides (nt) in *Phlomis* for the *atpB-rbcL* spacer, 327–372 nt for the *psbA-trnH* intergenic spacer, 1295–1305 nt for the *rpl16* intron, 617–648 nt for the *rpl32-trnL* spacer, 912–942 nt for the *rps16* intron, 947–954 nt for the *trnK* intron, 821–851 nt for the *trnL-trnF* spacer, 744–778 nt for the *trnS-trnG* spacer, and 696–724 nt for the *trnT-trnL* spacer. The concatenated and aligned plastid matrix consisted of 126 individuals and 9473 nucleotide position characters, of which 16.96% were variable in the dataset (Table 1). The resulting combined cpDNA and nrDNA dataset contained 10,726 positions, of which 21.46% were variable sites (Table 1).

3.2. Phylogenetic analyses

The cpDNA, nrDNA, and combined cpDNA and nrDNA phylogenies all supported the monophyly of *Phlomis* s.l. (Figs. 2, 3 and S1–S8). The relationships based on the cpDNA-derived tree (Fig. 2,

S3 and S4) were better supported than the tree inferred using two nrDNA markers (Figs. S1, S5 and S6) as well as the combined cpDNA and nrDNA markers (Figs. S2, S7 and S8). Phylogenies derived from BI and ML analyses were generally concordant (Figs. S3–S8). The BI phylogeny from the combined cpDNA dataset is presented here, with nodal support values from both BI PP and ML BS (Fig. 2).

The monophyly of *Phlomoides* s.l. (including traditionally circumscribed *Eremostachys*, *Lamiophlomis*, *Metastachydium*, *Notochaete*, *Paraeremostachys*, *Pseuderemostachys*, and *Pseudomarrubium*) was strongly supported (1.00 and 99% for the BI-PP and ML-BS, respectively; the values are listed in the same order below; Fig. 2), and the genus can be divided into six major clades. All clades had high support values, with Clades I and II collectively sister to a group that includes Clades III, IV, V, and VI. Monophyly for most traditionally defined sections (*Filipendula* (Popov) Adylov et al., *Moluccelloides* (Bunge) Sennikov, *Paraeremostachys* (Adylov et al.) Sennikov, *Phlomoides* (Popov) Adylov et al., and *Thyrsiflorae* (Rech.) Ranjbar & Mahmoudi) was not supported. In addition, the Chinese species of *Phlomoides* as well as most series recognized by Hsuan (1977) were not monophyletic.

Clade I (“*Notochaete* clade” sensu Salmaki et al., 2012a) consists of the former genus *Notochaete* (Fig. 2). Clade II (1.00/98%) contains 34 taxa (out of the 44 accessions) and is the core group of Chinese *Phlomoides*. Species in Clade II included members of *Phlomoides* sect. *Phlomoides* plus two accessions of *Phlomoides rotata* (Benth. ex Hook.f.) Mathiesen, which previously was defined as the monotypic genus *Lamiophlomis*. At the series level, 29 species from 11 series sensu Hsuan (1977) were included in this clade. Of the 11 series, five are monotypic but each contains only one individual in the present study (i.e., *Atropurpureae*, *Jeholenses*, *Paohsingenses*, *Pedunculatae*, *Umbrosae*), while the monophyly of the remaining six series (i.e., *Dentosae*, *Franchetianae*, *Megalanthae*, *Melananthae*, *Tatsienenses*, *Tibeticae*) was not supported. In addition, five unplaced species [*Phlomis brevidentata* H.W. Li (treated as a synonym of *Phlomoides breviflora* (Benth.) Kamelin & Makhm. in this study, see Taxonomic treatment section), *Phlomoides breviflora*, *P. macrophylla* (Benth.) Kamelin & Makhm., *P. nyalamensis* (H.W. Li) Y. Zhao & C.L. Xiang, and the recently described new species *P. liangwangshanensis* Y. Zhao, H.L. Zheng & C.L. Xiang] were recovered within this clade.

Clades III, IV, V, and VI collectively formed a clade. Clade III (Fig. 2; 1.00/100%) is comprised of seven taxa from three series of the section *Phlomoides*. *Phlomoides tuvunica* (A. Schroet.) Kamelin, Adylov & Makhm., which has not been placed in any series previously, was also recovered within Clade III. Clade IV (Fig. 2; 1.00/100%) is composed of species from two series. Two individuals of

P. oreophila (Kar. & Kir.) Adylov, Kamelin & Makhm. were not sister to each other in the cpDNA phylogenetic tree (Fig. 2), but were resolved as monophyletic in the nrDNA phylogenetic tree (Fig. S1). Series *Alpinae* was nested within ser. *Canescentes*. Clade V contains eight taxa, the traditionally defined monotypic genus *Metastachydium* was sister to another subclade consisting of five species from series *Tuberosae*, plus *P. adylovii* Lazkov, which has not been assigned to a series. Most species within Clade VI were members of the traditionally defined genus *Eremostachys*, except for *P. brachystegia* (Bunge) Adylov, Kamelin & Makhm., which was placed within *Phlomis* s.l. Species within Clade VI are from six sections (*Filipendula*, *Moluccelloides*, *Paraeremostachys*, *Pseuderemostachys* (Popov) Lazkov, *Thyrsiflorae*, and *Phlomoides*) and 13 series, of which seven series are monotypic (*Brachystegiae*, *Campanulatae*, *Fulgentes*, *Integrifoliae*, *Molucceliformes*, *Pauciflorae*, *Tuberosae*). The monophyly of the remaining six series (*Cordatae*, *Gymnocalyces*, *Laciniatae*, *Ovalifoliae*, *Rhodantheae*, *Speciosae*) was not supported. In addition, *P. sewerzovii* (Herder) Mathiesen (formerly of the monotypic genus *Pseuderemostachys*) was sister to *P. eremostachydioides* (Popov) Y. Zhao & C.L. Xiang (formerly from the monotypic genus *Pseudomarrubium*), together embedded within Clade VI.

In the nrDNA phylogenetic tree (Figs. S1, S4 and S5), only Clades I, III, and VI were recovered as monophyletic. A comparison of plastid and nuclear trees was performed to identify discrepancies between them (Fig. S9). The cpDNA data supported Clade I as a sister to Clade II, but nrDNA data placed Clade I as a sister with all other five Clades. Another major difference is that Clade III is sister to a large clade composed of Clade IV, V, and VI in the cpDNA tree, but formed a sister group with Clade VI in the nrDNA tree. In addition, Clade II and Clade IV were grouped together in the nrDNA tree.

In the combined cpDNA and nrDNA phylogenetic tree (Figs. S2, S7 and S8), the monophyly of six major clades were supported as the same in the cpDNA trees (Figs. 2, S3 and S4), and the topology of most clades was also congruent with the cpDNA phylogenetic tree, but with the lower overall support values.

4. Discussion

4.1. Circumscription and phylogenetic relationships of *Phlomoides*

This study represents the most comprehensive molecular phylogenetic survey of *Phlomoides*, in terms of both taxon sampling and number of markers, to date (Salmaki et al., 2012a; Zhao et al., 2023a,b). This affords the opportunity to examine the phylogeny,

Table 1
Statistics for phylogenetic analysis datasets.

Datasets	No. Taxa	Nucleotides (with ambiguous sites excluded) [bp]	GC content (%)	No. constant sites [bp]	No. variable sites [bp]	No. parsimony-informative sites [bp]
<i>atpB-rbcL</i>	126	2424	39.3	2177 (89.81%)	247 (10.19%)	157 (6.48%)
<i>psbA-trnH</i>	126	452	32.7	359 (79.42%)	93 (20.58%)	58 (12.83%)

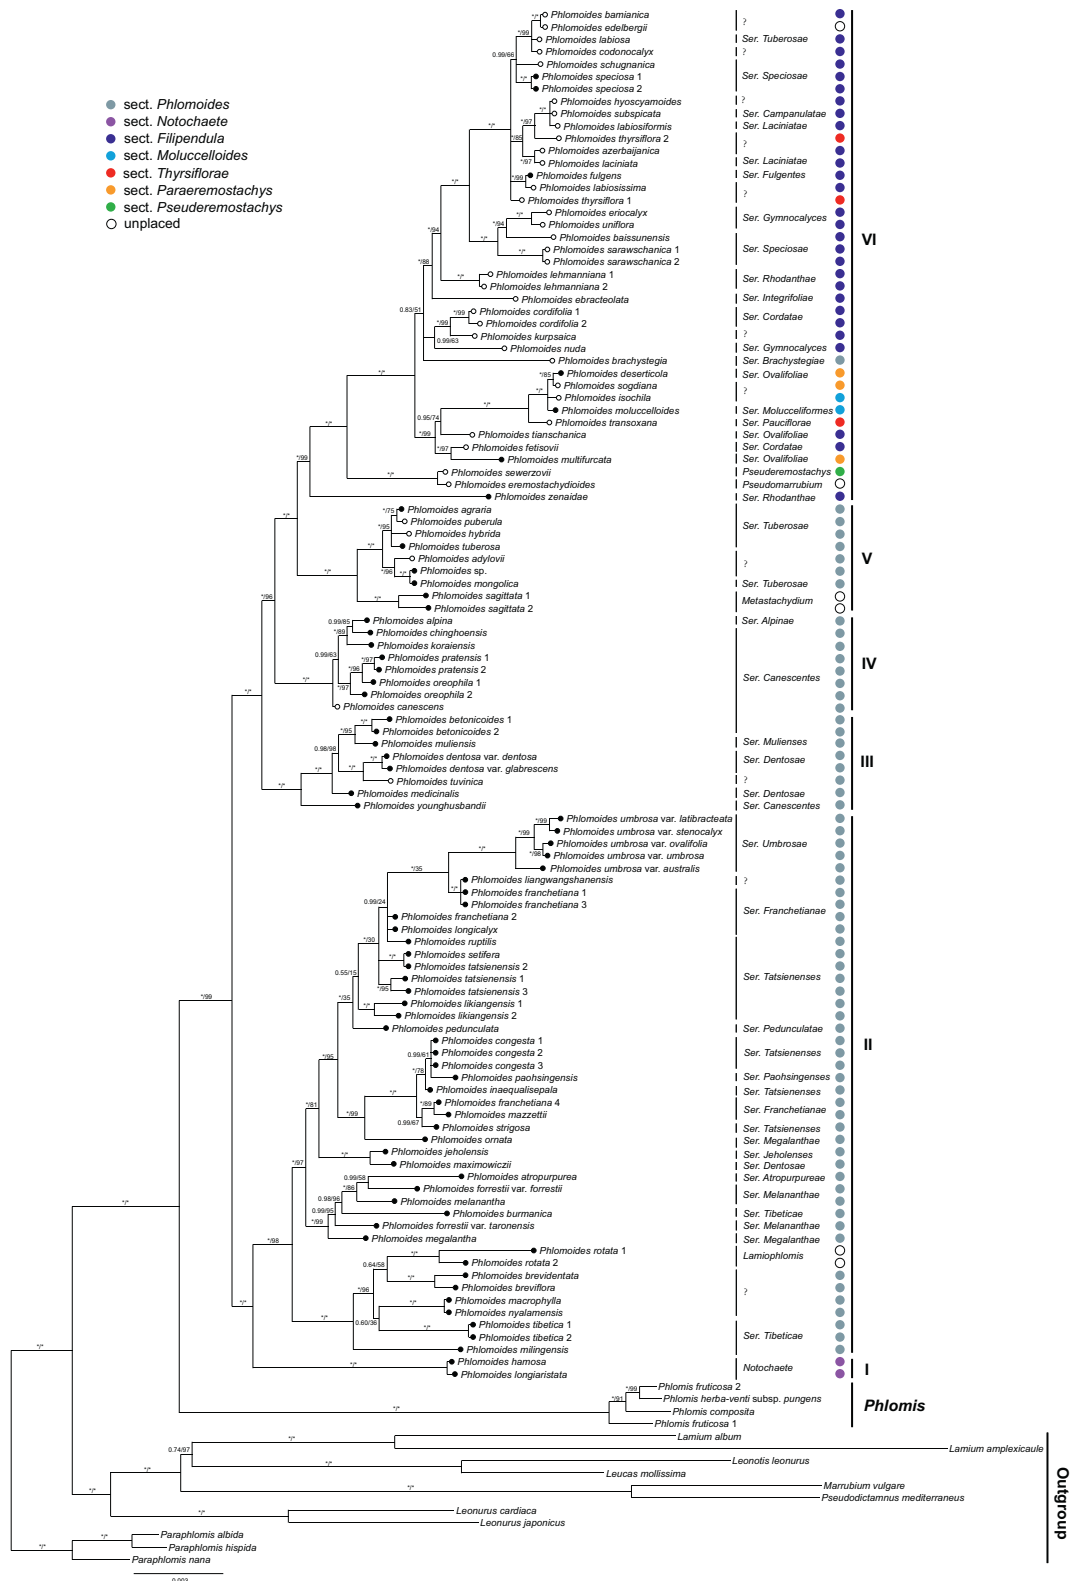

Fig. 2. Phylogeny of *Phlomis* inferred using Bayesian inference (BI), based on the combined plastid dataset. Support values displayed above branches follow the order BI-PP/ML-BS (“*” indicates PP = 1.00 or BS = 100%, solid circles indicate species occurring in China, hollow circles indicate species not in China). Sectional classification of *Phlomis* is based on Kamelin and Machmedov (1990a), Sennikov and Lazkov (2013), Lazkov and Sennikov (2015), and Ranjbar and Mahmoudi (2015). Series classification of *Phlomis* is based on Popov (1926, 1940), Knorrning (1954) and Hsuan (1977). Multiple accessions of the same species are numbered according to Table S1.

Fig. 3. Select morphological characters mapped onto the Bayesian consensus tree. Symbols are filled squares (F) or open squares (O). Characters are **A.** Habit: herb = O, shrub = F; **B.** Basal leaves: absent = O, present = F; **C.** Division of leaves: simple = O, lacinate to bipinnatisect = F; **D.** Calyx shape: tubular = O, campanulate or infundibular = F; **E.** Bracts shape: straight = O, hooked = F; **F.** Upper corolla lip shape: galeate = O; erect = F; **G.** Upper corolla beard color: white = O, brown to black = F; **H.** Nutlet apex: glabrous or with sparsely branched trichomes = O, dense, simple, long trichomes = F.

circumscription and infrageneric relationships of this taxonomically challenging group. Although several recent studies have clarified the boundaries of *Phlomis*, no study has combined intensive sampling of both *Phlomis* and related genera.

We confirmed the inclusion of seven traditionally defined genera (i.e., *Eremostachys*, *Lamiophlomis*, *Metastachydium*, *Notochaete*, *Paraeremostachys*, *Pseuderemostachys* and *Pseudomarrubium*) within *Phlomis*. Monophyly of the broadly defined *Phlomis* was well supported in all analyses, and six primary clades were inferred based on cpDNA data (Figs. 2, S3 and S4), yielding trees with higher resolution and better-supported relationships than the nrDNA phylogenetic tree (Figs. S1, S5 and S6) and combined cpDNA and nrDNA data (Figs. S2, S7 and S8). The recovered major clades were also supported by several morphological differences, such as the presence of basal leaves, trichomes on the apices of nutlets, and the color of trichomes within the upper corolla lip. Therefore, the BI topology from the combined cpDNA dataset will be the primary tree for discussing phylogenetic relationships.

Clade I comprises two species previously treated as the genus *Notochaete* (Fig. 2). Using three cpDNA sequences (*trnL* intron, *trnL-trnF* spacer, and *rps16* intron), Scheen et al. (2010) found *Notochaete hamosa* Benth. (the type species of *Notochaete*) nested within *Phlomis*, and later Mathiesen et al. (2011) formally transferred *Notochaete* into *Phlomis*. This relationship was recovered by later studies based using additional DNA markers (Bendiksby et al., 2011; Salmaki et al., 2012a; Zhao et al., 2023a,b). The genus forms a separate lineage and has been defined as the “*Notochaete*” clade (Salmaki et al., 2012a) or “*Notochaete*” group (Zhao et al., 2023a), but *Notochaete* has not been placed within any section because of insufficient taxon sampling within *Phlomis*. Our findings are congruent with previous studies but yield new information about the position of *Notochaete*, resolving it as sister to Clade II (Fig. 2), which in the cpDNA tree is composed mostly of Chinese species distributed in the Himalayan and Hengduan Mountains (Clade II; Fig. 2), or sister to all other species of *Phlomis* in the nrDNA tree (Fig. S1).

Several features support the close relationship between Clades I and II in the cpDNA phylogeny. For example, most species in the two clades grow in forested habitats, and most species have nutlets that are glabrous and lack basal leaves. However, Clade I is sister to all other species of *Phlomis* in the nrDNA phylogeny (Fig. S1). In this study, despite the position of the “*Notochaete*” group (Clade I) being discordant between the chloroplast and nuclear phylogenies, the monophyly of the two species is strongly supported. Morphologically, several distinct characters support the *Notochaete* group, including hooked floral bracts and calyx spines (vs. needlelike or lanceolate bracts and calyx teeth with needlelike spines at apex). In addition, these two species also have the smallest flowers within *Phlomis* (less than 1 cm vs. 1.5–5 cm long). In light of these synapomorphies we will refer to this clade as *P.* sect. *Notochaete* (see Taxonomic treatment section) to accommodate its systematic position within the genus.

Clade II is composed of 29 species and 5 varieties that are mostly distributed in forests or alpine steppe regions of the QTP, Hengduan Mountains, and northern China. There are three potential synapomorphies for this clade: species generally have linear-tuberous or woody fibrous roots; lack basal leaves, and have glabrous nutlets. In addition, most species in this clade are tall herbs usually higher than 1 m, sometimes up to 2 m, while species in the other clades are much shorter. As shown in Fig. 2, at least five subclades can be recognized within Clade II based on the cpDNA phylogeny, but one species, *P. pedunculata* (Y.Z. Sun) Kamelin & Makhm., is sister to Clade III (0.67/35%) in the nrDNA phylogeny, indicating topological incongruence probably attributed to hybridization and chloroplast

capture, as reported in *Phlomis* (the sister group of *Phlomis*) (Albaladejo et al., 2005) and other genera in Lamiaceae (Drew and Sytsma, 2013; Drew et al., 2014; Deng et al., 2015; Walker et al., 2015; Hu et al., 2018; Celep et al., 2020). Geographically, many species within this clade have a sympatric distribution, and species in the clade are quite variable morphologically. Thorough morphological investigation and a detailed molecular population-level study are needed to resolve species relationships within this group.

Clades III, IV, V, and VI form a large clade sister to Clades I and II. All species in Clade III–VI are characterized by having basal leaves. Clade III contains six species that are distributed in steppe or alpine steppe regions of the QTP, Hengduan Mountains, and the Mongolia Plateau.

Clade IV consists of six species distributed in steppe or alpine steppe regions of Central Asia and the Mongolia plateau, and all species have cordate basal leaves. The corolla morphology of plants in this clade is distinct, i.e., the upper lip is bent at a right angle relative to the tube (Fig. 1G) (vs. upper lip usually straight or slightly curved downward, but not bent downward in other clades; Fig. 1M). In comparison with taxa from Clades III and V, the corolla of taxa in Clade IV have longer tubes and shorter limbs (tube three times vs. two times longer than limb). Within Clade IV, *Phlomis pratensis* (Kar. & Kir.) Adylov, Kamelin & Makhm. and *P. canescens* have ovate-oblong floral leaves, while the other species in Clade IV have upper floral leaves narrowly linear, and lower floral leaves linear-lanceolate (Fig. 1G). *Phlomis pratensis* has double-toothed calyx teeth (Fig. 1A), while the calyx teeth are rounded in the other five species. The nutlet morphology of species in this clade is also variable, with some taxa having sparse trichomes at the apex (i.e., *P. alpina* (Pall.) Adylov, Kamelin & Makhm., *P. canescens*, *P. chinghoensis* (C.Y. Wu) Kamelin & Makhm. and *P. oreophila* (Kar. & Kir.) Adylov, Kamelin & Makhm.) or glabrous nutlet apices (i.e., *P. pratensis*, *P. koraiensis* (Nakai) Kamelin & Makhm.). It is notable that *P. koraiensis* has six downward appendages at the filament base, which is a unique character within the genus; all other species within Clade IV have two appendages at the filament base or lack appendages (Y. Zhao pers. obs.).

Clade V is composed of eight species mainly distributed in steppe or alpine steppe regions of Central Asia and the Mongolian Plateau. Possible synapomorphies for this clade include tuberous roots that are globose to fusiform (Fig. 1I), +/- sagittate basal leaves, triangular floral leaves, and nutlets either glabrous or with branched trichomes. In this study, one undetermined individual (*Phlomis* sp.), collected from Hebei Province in China, is morphologically similar to *Phlomis dentosa* var. *glabrescens* (Danguy) C.L. Xiang & H. Peng. However, an individual of *Phlomis dentosa* var. *glabrescens*, collected from Gansu Province, grouped with the type variety (*P. dentosa* var. *dentosa*) within Clade III, while *Phlomis* sp. grouped with *P. mongolica* (Fig. 2; 1.00/100%; Fig. S1; 0.93/100%) within Clade V. After comparing the external morphology of the two specimens, we found that *Phlomis* sp. has floral leaves similar to *P. mongolica* (floral leaves with no obvious petiole and blades often broad, length-width ratio less than 2), while *P. dentosa* var. *glabrescens* and *P. dentosa* var. *dentosa* have similar floral leaves (floral leaves with petiole ca. 5 mm long, blade often longer, length-width ratio about 2.5–4). Geographically, *Phlomis* sp. and another morphologically similar species (*P. mongolica*) within Clade V are distributed in Hebei, Beijing, and eastern Inner Mongolia in China, while *P. dentosa* var. *glabrescens* and *P. dentosa* var. *dentosa* are distributed in western Inner Mongolia Gansu, Qinghai and Ningxia provinces in China. The collection of *Phlomis* sp. likely represents a new species, but further morphological studies are needed before official recognition.

Clade VI is a well-supported clade (Fig. 2; 1.00/98%), with most species belonging to the previously defined genus *Eremostachys*. In our study, this clade consists of 35 species that are distributed in desert, desert steppe, or mountain steppe regions from Central Asia to western Asia. Morphologically, species in this clade usually have basal leaves (Fig. 1B and C), nutlets generally have long simple trichomes, and filaments often have comblike appendages at the base (Fig. 1N, arrow). Within clade VI, *Phlomoidea zenaidae* (Popov) Adylov, Kamelin & Makhm. diverges first and is sister to the remaining taxa. Morphologically, this species can be distinguished from other species within the clade by having glabrous nutlets. In addition, the upper corolla lip morphology of *P. zenaidae* is unique. In other species within Clade VI, the posterior corolla lips have irregularly denticulate margins and bearded insides, but *P. zenaidae* has entire posterior corolla lips with sparse trichomes on the margins, similar to *Phlomis*. The next diverging lineage is *P. sewerzovii*. Morphologically, the upper lip of corolla of *P. sewerzovii* is erect and 2-lobed, with short stamens that are included within the corolla tube. These characters are rare in the genus with only three species, *P. boraldaiica* A.L. Ebel, *P. sagittata* (Regel) C.L. Xiang & Y. Zhao (Fig. 1F), and *P. sewerzovii*, displaying these features (Fig. 3, character F). *Phlomoidea sewerzovii* and *P. boraldaiica* were members of *P. sect. Pseuderemostachys*, while *P. sagittata* was nested within Clade V. Clade VI is the largest major clade recovered, with six species distributed in China, and the remaining species ranging from central to western Asia. In comparison with species distributed in southwest China, the Hengduan Mountains, and the Himalayas, the species in this clade mostly grow in arid habitats and possess arid-adapted characters such as densely lanate stems, calyces, and nutlets (Fig. 1B), as well as napiform roots (Fig. 1J and K). Although several well-supported subclades can be recognized within this clade, relationships among species await more detailed taxon sampling.

4.2. Implications for infrageneric classification of *Phlomoidea*

Prior to 1990, *Phlomoidea* was placed within *Phlomis* s.l. as a section (Bentham, 1832–1836; Briquet, 1897; Hsuan, 1977), and *Eremostachys* was considered as a separate genus closely allied to *Phlomis*. Therefore, most names of the infrageneric categories (sections and series) of *Phlomoidea* originated from Popov's (1940) classification system of *Eremostachys* and Popov's (1926) and Knorring's (1954) classification system of *Phlomis* sect. *Phlomoidea*. In resurrecting the genus *Phlomoidea*, Adylov et al. (1986) divided the genus into two sections, *P. sect. Phlomoidea* and *P. sect. Fili-pendula*. Now, since the circumscription of *Phlomoidea* has drastically changed, existing infrageneric classifications are no longer sufficient.

Molecular phylogenetic reconstructions of *Phlomoidea* have gradually delimited the boundaries of the genus and identified allied genera (Pan et al., 2009; Scheen et al., 2010; Bendiksby et al., 2011; Mathiesen et al., 2011; Salmaki et al., 2012a; Zhao et al., 2023a,b). These insights were used as a basis for a revised classification of *Phlomoidea* and several new sections were proposed. For example, based on Salmaki et al.'s (2012a) molecular phylogenetic analyses, Sennikov and Lazkov (2013) established three new sections, *P. sect. Eremostachys*, *P. sect. Moluccelloidea*, and *P. sect. Par-aeremostachys*. Later, Lazkov and Sennikov (2015) established the monotypic section *P. sect. Pseuderemostachys* based on its unique characters by having short stamens barely exerted from the corolla. Ranjbar and Mahmoudi (2015) proposed a new section, *P. sect. Thyrsiflorae* (Rech.) Ranjbar & Mahmoudi, which is consistent with *Eremostachys* sect. *Thyrsiflorae* Rech. f. To date, seven sections have been proposed within *Phlomoidea*. Here, we did not adopt the concept of *P. sect. Eremostachys* (Bunge) Sennikov because this

section was equal to the “*Eremostachys laciniata* core group” (Salmaki et al., 2012a), and members of this group were not clearly defined.

The classification scheme proposed by Hsuan (1977) divided Chinese *Phlomoidea* (= *Phlomis* sect. *Phlomoidea*) into two subsections and 17 series. This is the only infrageneric classification system for *Phlomoidea* in China, but was largely based upon Popov's (1926) and Knorring's (1954) classifications. Hsuan (1977) recognized two subsections for Chinese *Phlomoidea*, subsect. *Anisostyleae* M. Pop. (style unequally 2-cleft at apex) and subsect. *Isostyleae* M. Pop. (style equally 2-cleft at apex). In this study, we sampled 90 taxa of *Phlomoidea* representing 28 series, but the monophyly of most series was not supported (Figs. 2 and S1). Another major difference between the proposed system of Hsuan (1977) and currently recognized *Phlomoidea* is that several former genera are now treated within *Phlomoidea* (i.e., *Eremostachys*, *Lamiophlomis*, *Metastachydium*, *Notochaete*). In the updated treatment of *Lamiaceae* in *Flora of China* (Li and Hedge, 1994), these genera were also segregated from *Phlomoidea*.

In this study, we have taken a first step towards clarifying the circumscription of *Phlomoidea*. This includes extensive sampling of Chinese taxa (51 species and 6 varieties, accounting for 88% of Chinese species) as well as 33 species from central Asia, western Asia, Europe, and Mongolia, representing all six aforementioned sections. In the resulting tree, six major clades of *Phlomoidea* are recognized (Fig. 2). However, the species composition in each clade is not consistent with, nor do any of the six major clades match, previously established sections.

Establishing a tenable infrageneric classification for *Phlomoidea*, as with any large and complex genus, is a necessary first step towards a stable taxonomy. Unfortunately, previous circumscriptions of *Phlomoidea* have not resulted in a usable system, since neither the traditional sectional nor series classifications were supported here. Because this study is focused on taxa native to China, we only established one new section to accommodate the systematic placement of the “*Notochaete*” clade (Clade I) based on molecular data and unique morphological characters (see Taxonomic treatment section). Future studies involving increased taxon sampling, high-throughput sequencing, as well as morphological investigation are needed to provide more evidence for establishing a stable classification system for *Phlomoidea* s.l.

4.3. The search for useful morphological characters

Phlomoidea is morphologically very diverse, and it is difficult to identify clear synapomorphies for most clades from our phylogenetic analyses (except Clade I in cpDNA phylogenies; Fig. 2). The major reasons are that a detailed morphological study for the genus is lacking, and morphological characters supporting the clades found here are mostly unknown or limited. Although trends of some selected morphological characters corroborate the relationships based on the cpDNA phylogenetic tree, morphological synapomorphies are difficult to identify for most clades. The search for synapomorphies, especially in Clades II and VI, remains challenging given the ample morphological variation exhibited by species within each clade.

The traditional taxonomic framework of Chinese *Phlomoidea* (Hsuan, 1977) is based on external morphological characters, such as the presence/absence of basal leaves, the indumentum on nutlets and leaves, flower size, calyx teeth shape, whether the 2-cleft style apices are equal/unequal, and whether stamens have basal appendages. The selection of these characters was based on observation of herbarium specimens, and some characters are highly variable in the field. During the past five years, we have investigated most species at the population-level in the field,

dissected flowers and calyces, and observed and compared trichome morphology using light microscopy and scanning electron microscopy methods (unpublished data).

Here we mapped eight morphological characters (Fig. 3) onto the cpDNA tree; phylogenetic inferences imply that at least some of these characters have significant taxonomic utility. For example, habit (Fig. 3, character A) is the most reliable character to distinguish *Phlomooides* (herb; Fig. 4A) from the sister group *Phlomis* (shrub; Fig. 4B). Within *Phlomooides*, calyces with hooked spines (Fig. 3, character E; Fig. 4J) are unique to Clade I and an absence of basal leaves (Fig. 3, character B) is a potential synapomorphy of both the combined Clades I and II. Although *P. rotata*, *P. tibetica* (C. Marquand & Airy Shaw) Kamelin & Makhm., *P. milingensis* (C.Y. Wu & H.W. Li) Kamelin & Makhm. and *P. atropurpurea* (Dunn) Kamelin & Makhm. within Clade II usually have rosetted leaves, this character likely evolved as an adaptation to high alpine scree ecosystems. Clade VI is characterized by taxa having long simple trichomes at the apex of nutlets (Fig. 4O), while in Clades I–V, nutlet apices are usually glabrous or rarely have sparsely branched trichomes (Fig. 4P). This character is also correlated with geographical patterns; species in Clade VI are distributed in central to western Asia, while species in Clade I–V are mainly distributed in southwest China to the eastern Himalayas and eastern Central Asia.

Some characters are found to be confined to a few species. For example, campanulate or infundibular calyx tubes (Fig. 4H) only occur in *P. isochila* (Pazij & Vvied.) Salmaki and *P. moluccelloides* (Bunge) Salmaki, while calyx tubes in other species are tubular. Another example is that only four high-altitude endemic species in Clade II have brown to black hairs (Fig. 4N) inside the upper corolla lip. This is perhaps a morphological adaption to pollinators. To date, detailed morphological, anatomical, and palynological studies of the genus have not been conducted and available data is limited. The discovery of new and useful taxonomic characters is strongly needed for establishing a predictable infrageneric classification system.

5. Taxonomic treatment

Based on our molecular phylogenetic analyses, morphological investigation, specimen examination, as well as previous studies, we make the following nomenclatural updates, including a new section, three new combinations, and three new synonyms of *Phlomooides* in China.

Phlomooides Moench, Methodus: 403. 1794. – Type: *P. tuberosa* (L.) Moench.

= *Eremostachys* Bunge in Ledebour, Fl. Altaic. 2: 414. 1830. – Type: *E. laciniata* (L.) Bunge.

= *Lamiophlomis* Kudô in Mem. Fac. Sci. Taihoku Imp. Univ. 2: 210. 1929. – Type: *L. rotata* (Benth. ex Hook. f.) Kudô.

= *Metastachydium* Airy Shaw ex C.Y. Wu & H.W. Li in Acta Phytotax. Sin. 13(1): 73. 1975. – Type: *M. sagittatum* (Regel) C.Y. Wu & H.W. Li.

= *Notochaete* Benth. in Wallich, Pl. Asiat. Rar. 1: 63. 1830. – Type: *N. hamosa* Benth.

= *Paraeremostachys* Adylov, Kamelin & Makhm. in Novosti Sist. Vyssh. Rast. 23: 112. 1986. – Type: *Pa. phlomooides* (Bunge) Adylov, Kamelin & Makhm.

= *Pseuderemostachys* Popov in Novye Mem. Moskovsk. Obshch. Isp. Prir. 19: 148. 1941 ('1940'). – Type: *Ps. sewerzovii* (Herder) Popov.

= *Pseudomarrubium* Popov, Bot. Mater. Gerb. Bot. Inst. Komarova Akad. Nauk SSSR. 8: 75. 1940. – Type: *Ps. eremostachydioides* Popov.

Phlomooides* sect. *Notochaete Y. Zhao, Y. Salmaki & C.L. Xiang, **comb. & stat. nov.** 钩萼草组 (新拟) – Type: *Phlomooides hamosa* (Benth.) Mathiesen (≡ *Notochaete hamosa* Benth.).

Species in this section. – *P. hamosa* (Benth.) Mathiesen, *P. longiaristata* (C.Y. Wu & H.W. Li) Salmaki.

Notes. – *Phlomooides hamosa* and *P. longiaristata* were included in the former genus *Notochaete* (Li and Hedge, 1994) until Mathiesen et al. (2011) and Salmaki et al. (2012a) transferred them to *Phlomooides*. This section is characterized by having hooked calyx lobes (Fig. 4J), hooked bracts, and flowers less than 1 cm long (vs. calyx lobes and bracts abruptly or gradually narrowed to a short spinose apex (Figs. 1P and 4I), and flowers 1.5–5 cm long).

Phlomooides taronensis (C.Y. Wu) Y. Zhao & C.L. Xiang, **comb. nov. & stat. nov.** 独龙草糙苏 (新拟) ≡ *Phlomis forrestii* Diels. var. *taronensis* C.Y. Wu, Fl. Yunnan. 1: 612. 1977. – Type: CHINA. Yunnan Province: Gongshan, Taron-Taru divide, valley of Bucahwang, margin of bamboo thickets, elev. 2600 m, 3 September 1938. T.T. Yu 20094 (Holotype: KUN, 2008620!; Isotypes: A, 00001406!, PE, 00031197!).

Wu et al. (1977) considered this a variety of *Phlomooides forrestii* (= *Phlomis forrestii*) and differentiated from the typical variety (*P. forrestii* var. *forrestii*) by its ovate or elliptic floral leaves, subcordate, rounded or wedge-shaped base, the margin callous-crenate or toothed (vs. floral leaves ovate to elliptic, base cordate, margin crenate or serrate-crenate). At the same time, on one duplicate of the type specimen (PE, 00031197!), Wu et al. (1977) also commented that the variety *taronensis* is morphologically similar to *P. melanantha* (Diels) Kamelin & Makhm. (= *Phlomis melanantha* Diels), but can be distinguished by having stellate hairs on upper stems, and double-toothed calyx teeth. *Phlomooides melanantha* has glabrous stems and emarginated calyx apices. Originally, Wu also considered this collection a new species. On the holotype (KUN, 2008620!) duplicate (PE, 00031197!) sheets, he proposed a name “*Phlomis taronensis* C.Y. Wu sp. nov.” on 22 April 1964, but subsequently, he published it as a variety of *Phlomis forrestii* (Wu et al., 1977). In the updated treatment of Lamiaceae in *Flora of China* (Li and Hedge, 1994), the variety *taronensis* was transferred to the typical variety without any explanation.

In this study, all three morphologically similar species (*Phlomooides taronensis*, *P. megalantha*, *P. forrestii*) were included for analyses. Phylogenetically, those species are grouped in Clade II (Fig. 2), but *P. taronensis* is sister to a subclade consisting of *P. burmanica*, *P. melanantha*, *P. forrestii* and *P. atropurpurea*. Based on our field investigations as well as specimen examinations, *P. taronensis* has lanceolate bracts (vs. rigid, subulate bracts in *P. megalantha* and *P. forrestii*). We here propose that *Phlomis forrestii* var. *taronensis* be elevated to species and formally transfer it to *Phlomooides*.

Phlomooides nyalamensis (H.W. Li) Y. Zhao & C.L. Xiang, **comb. nov.** 聂拉木草糙苏 (新拟) ≡ *Phlomis nyalamensis* H.W. Li in Fl. Xizang. 4: 157. 1985. – Type (designated here by Y. Zhao & C.L. Xiang): CHINA. Xizang: Nyalam County, Zhangmu, on the way from Lixin to Xuebugang, open spaces in forests, elev. 2700–2800 m, 29 June 1975, Qinghai-Xizang Comp. Exped. 6622 (Holotype: KUN, 1218985!; Isotype: KUN, 1218984!).

Li (1985) published the name based on specimens collected from Nyalam, Tibet (Xizang), China, and placed the species within *Phlomis*. Based on molecular phylogenetic studies (Pan et al., 2009; Mathiesen et al., 2011; Salmaki et al., 2012a), Xiang et al. (2014) proposed 11 combinations for Chinese *Phlomooides* but omitted this species. Here we propose a new combination.

Phlomooides nana (C.Y. Wu) Y. Zhao & C.L. Xiang, **comb. nov.** 侏儒草糙苏 (新拟) ≡ *Phlomis nana* C.Y. Wu, Fl. Xizang. 4: 154. 1985. –

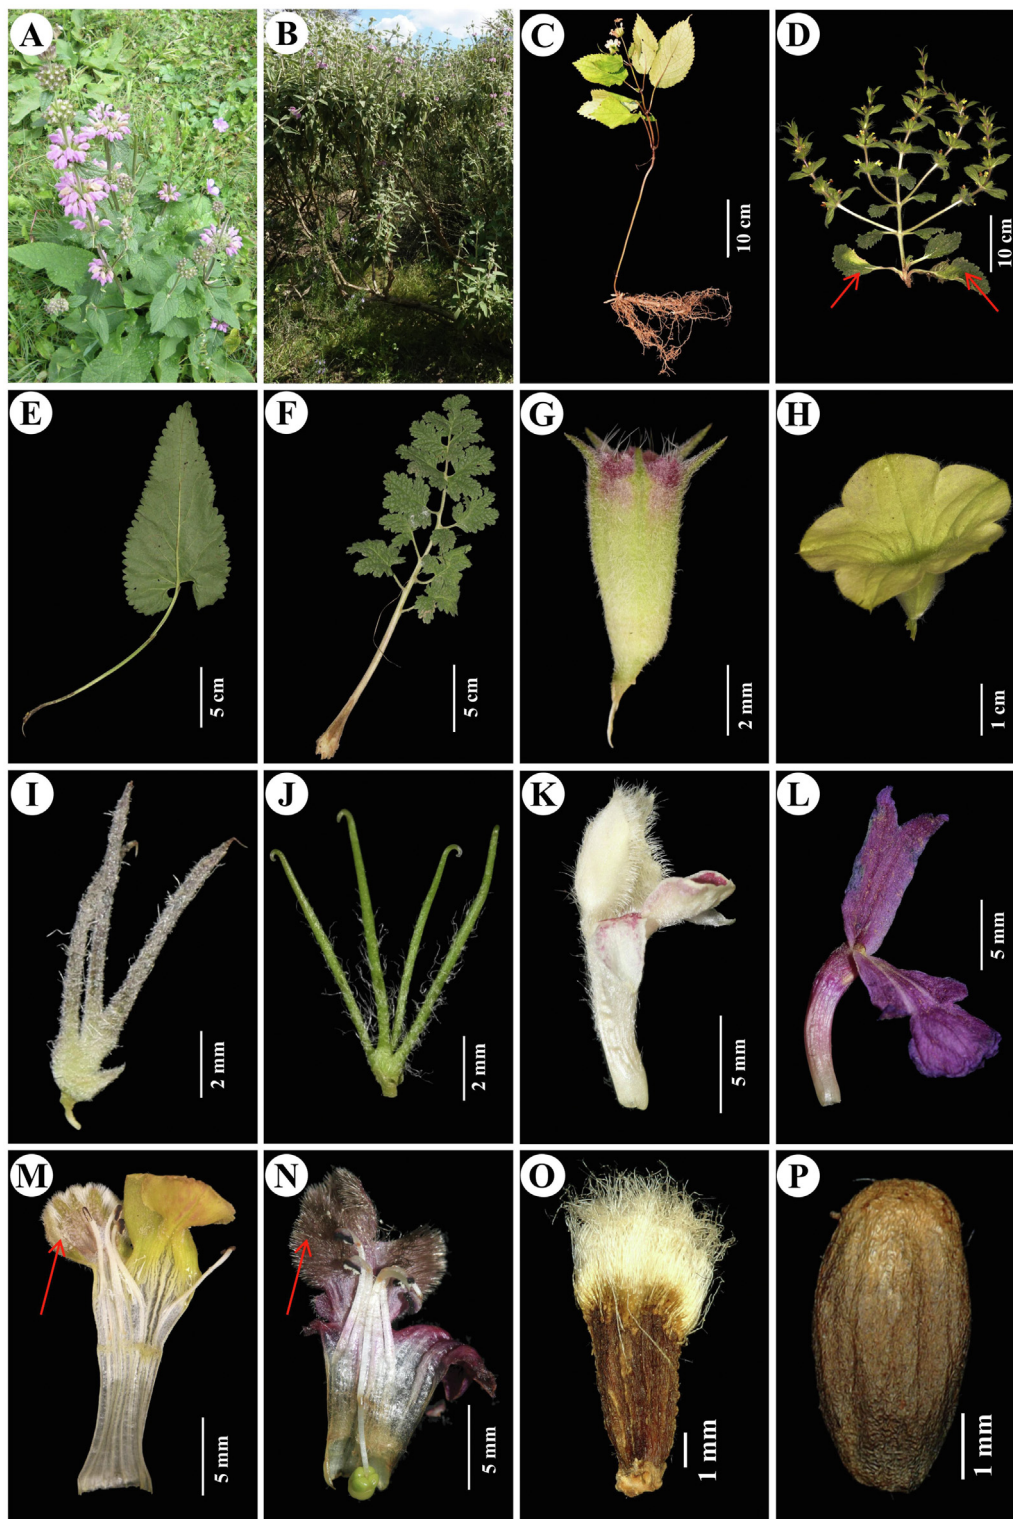

Fig. 4. Selected morphological characters from Fig. 3. **A.** *Phlomoides pratensis*, representing an herb, **B.** *Phlomis composita*, representing a shrub; **C.** *Phlomoides pedunculata*, lacking basal leaves; **D.** *P. multifurcata*, arrow showing basal leaves; **E.** Simple basal leaf of *P. mongolica*; **F.** Bipinnatisect basal leaf of *P. speciosa*; **G.** Tubular calyx of *P. umbrosa*; **H.** Infundibular calyx of *P. moluccelloides*; **I.** Straight bracts of *P. dentosa*; **J.** Hooked bracts of *P. hamosa*; **K.** Galeate upper lip of *P. ruptilis*; **L.** Erect and 2-lobed upper lip of *P. sagittata*; **M.** Dissected corolla of *P. multifurcata*, arrow showing the white trichomes; **N.** Dissected corolla of *P. nyalamensis*, arrow showing the brown to black trichomes; **O.** Nutlet of *P. moluccelloides*, with dense simple long trichomes on the apex; **P.** Glabrous nutlet of *P. franchetiana*. A–B, photographed by C.-L. Xiang; C–P, photographed by Y. Zhao.

Type (designated here by Y. Zhao & C.L. Xiang): CHINA. Xizang Province: Nyalam County, Zhangmu, open spaces in forests, elev. 2700–2800 m, 14 August 1972, *Tibetan Medic. Herb. Exped. 1180* (Holotype: PE, 0950649!; Isotype: PE, 0950648!).

Morphologically, *Phlomoides nana* is similar to *P. nyalamensis* and *P. macrophylla*, sharing similar emarginate calyx teeth and an upper corolla with brown to black hairs. But *P. nana* is readily distinguished from the latter two species by having short stems (shorter than 50 cm vs. stems usually 1–2 m tall).

Phlomoides dentosa (Franch.) Kamelin & Makhm. Bot. Zhurn. (Kiev) 75: 245. 1990. ≡ *Phlomis dentosa* Franch. Nouv. Arch. Mus. Hist. Nat., sér. 2 6: 123. 1883. – Type: CHINA. Inner Mongolia Province: June 1886, A. David 2731 (K, 000928261!).

= *Phlomoides similis* (Tscherneva) Kamelin & Makhm. Bot. Zhurn. (Kiev) 75: 243. 1990. ≡ *Phlomis similis* Tscherneva Rast. Tsentr. Azii 75: 243. 1990. **syn. nov.** – Type: CHINA. Qinghai Province: in fluxu superiore fl. Hoangho, oasis Guj-duj secus canales irrigatorios, elev. 2100 m, 14 June 1880, N.M. Przewalski s.n. (Holotype: LE, 01043000!; Isotype: LE, 01043001!).

In the protologue, **Tscherneva (1970)** stated that *Phlomoides similis* was morphologically similar to *P. younghusbandii* (Mukerjee) Kamelin & Makhm. and *P. admirabilis* (Tscherneva) Kamelin & Makhm., but differs by having triangular radical leaves with a cordate base and broad stems. However, we cannot find any differences between the type specimen of *P. similis* and *P. dentosa*. Geographically, *P. similis* is only known from the type locality (Qinghai Province), but *P. dentosa* is widely distributed in northern China (Inner Mongolia, Gansu and Qinghai). Here we synonymize the former species under *P. dentosa*.

Phlomoides dentosa (Franch.) Kamelin & Makhm. var. ***glabrescens*** C.L. Xiang & H. Peng ≡ *Phlomis dentosa* var. *glabrescens* Danguy, Bull. Mus. Natl. Hist. Nat. 17(5): 345. 1911. – Type: CHINA. Gansu Province: Si-Ning-Fou, elev. 2400 m, 18 July 1908, *Anonymus* 979 (P, 03284131!).

= *Phlomoides admirabilis* (Tscherneva) Kamelin & Makhm. ≡ *Phlomis admirabilis* Tscherneva, Rast. Tsentr. Azii 5: 56. 1970. **syn. nov.** – Type: CHINA. Gansu Province: near Kuan-gou-tschen, elev. 2300 m, 17 September 1901 (LE, 01041296!).

When publishing the species, **Tscherneva (1970)** indicated that *Phlomoides admirabilis* is closely related to *P. dentosa* var. *glabrescens*. Type specimens of both *P. dentosa* var. *glabrescens* and *P. admirabilis* were collected in Gansu, China at a similar altitude. After careful comparison, we cannot find any morphological differences based on type specimen examinations and field investigation. Thus, we treat *P. admirabilis* as a synonym of *P. dentosa* var. *glabrescens*.

Phlomoides breviflora (Benth.) Kamelin & Makhm. ≡ *Phlomis breviflora* Benth., Pl. Asiat. Rar. 1: 62. 1830. – Type: NEPAL. Gossain than (Gosainkund), *Benth in Wall. Cat. Herb. Ind. n. 2066* (K, 001115039!). 短花草糙苏 (新拟).

= *Phlomis brevidentata* H.W. Li, Fl. Xizang. 4: 157. 1985. **syn. nov.** – Type: CHINA. Xizang Province: Yadong, on the way from Yadong to Dingga, elev. 2850 m, 11 June 1975, *Qinghai-Tibet Exped. 750283* (Holotype: KUN, 1218974!; Isotype: PE, 00835569!, 00835570!).

When publishing the species, the author noted that *Phlomis brevidentata* was similar to *Phlomoides breviflora*, but differs by having denser trichomes on the leaves, bracts and calyces, and with no appendages at the base of the posterior 2 stamens (**Li, 1985**). During field work, we found that trichome density varies among individuals of the same species at different life stages. Generally, younger individuals often have denser trichomes but these gradually fall off from the older leaves and stems. A probable reason that *Phlomis brevidentata* was considered a different species is that the

type specimen was collected in the early flowering stage but the type specimen of *Phlomoides breviflora* was collected in the fruiting stage. As to the appendages at the base of the posterior 2 stamens, in the protologue of *P. breviflora*, **Bentham (1830)** only mentioned that “staminibus e tubo vix exsertis, filamentis nudis,” and never indicated that this species has appendages at the base of posterior stamens.

6. Conclusions

This study presents the first molecular phylogenetic analyses of *Phlomoides* in which taxa representative of the entire genus are included, and the monophyly of the redefined *Phlomoides* s.l. is confirmed. Six major clades were recognized, but the monophyly for most previously defined sections and series was not recovered. Eight morphological characters were found to be mostly consistent with the phylogeny and to have taxonomic significance. In addition, based on molecular and morphological data, a section, three combinations as well as three synonyms are newly proposed. Future studies should focus on the entire genus to propose a taxonomic revision and reclassification for *Phlomoides*.

Data availability statement

The datasets analyzed during the current study are available in the Figshare repository, [10.6084/m9.figshare.23936628](https://doi.org/10.6084/m9.figshare.23936628). Plant material and seeds used in this study can be obtained upon request from the corresponding author.
