Background: Temporary hypocalcemia is the most common complication in patients after total thyroidectomy. To date, according to the literature, various predictors of the above complication have been proposed, but none of them seems to be effective enough.

Objectives: The aim of this study was to develop a reliable predictive tool for biochemical hypocalcemia in the first 48 hrs after total thyroidectomy without central dissection by analyzing several parameters relevant to this operation and to suggest a new score.

Methods: A retrospective study was performed on patients who had undergone total thyroidectomy without central neck dissection from October 2017 until January 2018. Data were collected from 36 patients and studied if there was a statistically significant relationship between the risk of hypocalcemia and 10 preselected prognostic factors.

Results: The prognostic score was formed, which included the 6 factors that showed a statistically significant relationship. Moreover, an extensive check of the predictive value of the above score was performed. It was found, therefore, that at a value of 3 and above the sensitivity was 100%, the specificity 79.16%, the positive prognostic value (PPV) 70.58% and the negative predictive value (NPV) 100%.

Conclusions: High sensitivity of CaReBe'S TIP score makes it feasible to predict patients with postoperative hypocalcemia. High NPV would allow surgeons to exclude patients with a score less than 3 from supplementary calcium medication and achieve a shorter hospitalization for them.

Keywords: design, thyroidectomy, hypocalcemia, prognostic factors

Introduction

In Europe, thyroid surgery, regardless of the cause, is ranked third among operations in general surgery.¹ Total thyroidectomy is recommended according to the guidelines not only for malignant diseases² but for toxic and non-toxic benign multinodular goiter.³ Temporary hypoparathyroidism (19–38%) is by far the most common postoperative complication of total thyroidectomy.^{4,5} Biochemical hypoparathyroidism is the state when the concentration of parathormone (PTH) is under the lower limit according to the microbiological laboratory, accompanied by hypocalcemia. Typically, this limit is 12 pg/mL.⁶ It is worth noting that hypoparathyroidism, if not treated, always leads to hypocalcemia.

Therefore, it is important to develop a methodology that will be able to identify, in the best and fastest way, an imminent postoperative hypocalcemia. To date, many factors have been associated with the above complication in several studies, with the aim of predicting postoperative hypocalcemia before it even occurs. However,

none of them is quite effective by itself.⁵ The present study aimed to examine several preoperative and immediate postoperative factors, regarding their possible correlation with developing postoperative biochemical hypocalcemia in the first 48 hrs after total thyroidectomy. Consequently, a prognostic score could be created and the prophylactic medication for hypocalcemia would be prescribed only when it is necessary. The patients, whose calcium concentration would be maintained within normal range according to the predictive score, would be excluded from this treatment.

Patients and methods

This is a retrospective study and was conducted at the 3rd Surgical Clinic of the University General Hospital of Thessaloniki, "AHEPA", and the study was approved by the investigational review board of the Aristotle University of Thessaloniki. The records of adult patients who had undergone total thyroidectomy from October 2017 until January 2018 were examined after permission by the hospital's ethical committee. Patient written informed consent was acquired for all files-data of this study. All operations were performed by highly experienced surgeons. Inclusion and exclusion criteria were set to define accurately the target population.

Inclusion criteria:

- Patients who undergone total thyroidectomy without central neck dissection regardless of the thyroid disorder.

Exclusion criteria:

- Patients with re-implantation of at least one parathyroid gland (PGRIS score<4).⁷
- Patients with accidental removal of at least one parathyroid gland found in the histopathologic report (PGRIS score<4).⁷
- Patients with enlarged central lymph node or papillary thyroid carcinoma >1 cm (central neck dissection is performed in such cases).
- Patients with lateral neck dissection.
- Patients with previous thyroid, parathyroid, or other central neck operation.
- No previous medication affecting the calcium serum concentration (calcium supplementation, vitamin D, bisphosphonates, thiazides, denosumamb, bicarbonate, lithium, vitamin A, calcitonin, furosemide, glucocorticoids, estrogens, cinacalcet).⁸

Direct preventive medication is often recommended in these cases because are associated with high prevalence of temporary postoperative hypocalcemia.⁹

A total of 39 total thyroidectomies were performed during the study. However, a total of 36 adult patients were included in the study, since 3 of them met the exclusion criteria. Specifically, two had papillary thyroid carcinoma >1 cm and one was treated for osteoporosis that affected calcium concentration. The results of Orloff's et al statement on postoperative hypoparathyroidism and Edafe's et al systematic review and meta-analysis of predictors of post-thyroidectomy hypocalcemia were used after literature review. Ten factors were selected and studied for correlation with temporary hypocalcemia in the first 48 hrs, based on our clinical experience and the inclusion/exclusion criteria that were set.^{5,10} These factors are all preoperative, except the PTH which was controlled postoperatively (6 hrs after surgery). The factors studied were age, sex, thyroid gland size, multinodular goiter, retrosternal goiter, ultrasound image of calcifications, malignancy (<1 cm), thyroid function at initial diagnosis, preoperative total serum calcium concentration, and PTH's concentration after surgery. (Table 1)

Biochemical hypocalcemia was defined as a total serum calcium level <8.0 mg/dL corrected for albumin concentration, $Ca [corrected] = [0.8 \times \{normal\ albumin - patient\ albumin\} + serum\ Calcium]$ or ionized serum calcium <1.1 mmol/L, based on the physiological limits of the hospital's microbiological laboratory. All patients' calcium levels were corrected for albumin concentration. The under study complication was checked for all patients from the day of surgery until the second postoperative day (6, 24 and 48 hrs after surgery).

The patients were classified into those over and under 50 years old. For the size of the thyroid gland, the most recent ultrasound was taken into account in each patient, indicating whether the size of the gland was normal or not (normal dimensions: height 4 cm, width 15–20 mm, thickness 20–39 mm),¹¹ although the real thyroid volume is usually highly underestimated by this way.¹² In the same way, the data about the presence or not of multinodular and retrosternal goiter, as well as calcifications were collected. As retrosternal was defined a thyroid goiter in which any part of the gland extends below the thoracic inlet with the patient in the surgical position.¹³ Fine needle aspiration (FNA) was performed on patients with a suspicious nodule for malignancy. Based on the result of this test, which is imprinted with the Bethesda scale (1–6), patients were

Table 1 Demographic data per factor

Variables	With post-operative hypocalcemia (n=12)	Without post-operative hypocalcemia (n=24)
Age	>50: 9 ≤50: 3	>50: 19 ≤50: 5
Sex	Male: 1 Female: 11	Male: 7 Female: 17
Thyroid gland size	Large: 11 Normal: 1	Large: 12 Normal: 12
Multinodular goiter	Yes: 8 No: 4	Yes: 15 No: 9
Retrosternal goiter	Yes: 6 No: 6	Yes: 3 No: 21
Calcifications	Yes: 7 No: 5	Yes: 10 No: 14
Malignancy	Bethesda ≥4: 8 Bethesda <4: 3 and no FNA: 1	Bethesda ≥4: 6 Bethesda <4: 12 and no FNA: 6
Thyroid function at initial diagnosis	Pathologic: 10 Normal: 2	Pathologic: 9 Normal: 15
Preoperative calcium	<9: 7 ≥9: 5	<9: 3 ≥9: 21
PTH 6 hrs after surgery	<1.58: 10 ≥1.58: 2	<1.58: 9 ≥1.58: 15

ranked to those who had the lowest chance of suffering from thyroid malignancy (Bethesda 2–3) and those who were most likely or proven that have malignancy (Bethesda 4–6). It should be noted that patients who did not have an FNA test because there was no relevant clinical or imaging evidence were classified with those in the first category. Furthermore, thyroid function in the initial diagnosis was tested with thyroid stimulating hormone (TSH), classifying patients into euthyroid, hypothyroid and hyperthyroid. The preoperative serum calcium concentration was controlled during the patient's hospital admission the day before surgery. With a limit of 9 mg/dL preoperative calcium, patients were classified into two subcategories.¹⁴ Finally, information on whether or not the patients had normal serum levels of PTH was collected 6 hrs after surgery, according to the hospital's microbiology laboratory (1.58–6.03 pmol/L).

Statistical analysis

The SPSS 25 software was used. The sample was initially divided into two groups, depending on whether they had biochemical hypocalcemia in the first 48 hrs after the operation. Subsequently, statistical analysis was performed for each individual independent variable to ascertain if there was a statistically significant correlation between them and the under study complication. The above comparisons were performed with the odds ratio (OR) test ($p < 0.05$). Independent variables that displayed a statistically significant relationship to the risk of developing hypocalcemia were then included in the prognostic score. Finally, all patients were ranked according to the score and the sensitivity, the specificity, the PPV and the NPV for each possible value of the score were calculated.

Results

Out of 36 patients, 12 (33.3%) developed biochemical hypocalcemia in the first 48 hrs after total thyroidectomy. There was no statistically significant correlation between the dependent variable and age ($p = 0.777$), sex ($p = 0.184$), multinodular goiter ($p = 0.806$) and calcifications ($p = 0.348$). On the contrary, all the remaining factors significantly affect the risk of postoperative biochemical hypocalcemia. These factors are the large thyroid gland's size ($p = 0.032$), the ultrasound image of retrosternal goiter ($p = 0.021$), the hypothyroid or hyperthyroid patient's status ($p = 0.016$), the risk of malignancy based on a previous FNA test (Bethesda ≥4) ($p = 0.02$), the preoperative calcium concentration <9 mg/dL ($p = 0.007$) and the concentration of postoperative PTH <1.58 pmol/L ($p < 0.001$). (Table 2)

According to the above data, a prognostic score was developed, which would allow the early detection of temporary biochemical hypocalcemia after total thyroidectomy without central neck dissection. This included all the independent variables that displayed a statistically significant relationship with biochemical hypocalcemia. Overall, this consists of 6 prognostic factors. Each of them gives 1 point to the score (0–6 points). To achieve an easier memorization of the score, the name CaReBe'S TiP was given, which is an acronym from the initials of the included factors. (Table 3)

Moreover, diagnostic tests were performed for the CaReBe'S TiP score to determine whether this is reliable and useful. Sensitivity, specificity, PPV and NPV were calculated for each possible value of the score. It is worth noting, that for a score value ≥3 the sensitivity is

Table 2 Results with the use of odds ratio test

Independent variables	OR	P-value	Statistically significant relationship
1. Age >50	1.267	0.777	No
2. Sex	0.221	0.184	No
3. Multinodular goiter	1.2	0.806	No
4. Ultrasound image of calcifications	1.96	0.348	No
5. Large thyroid gland's size	11	0.032	Yes
6. Retrosternal goiter	7	0.021	Yes
7. Thyroid function in the initial diagnosis	8.33	0.016	Yes
8. Suspected or proven malignancy based on FNA test	6	0.02	Yes
9. Preoperative Calcium <9.00 mg/dL	9.8	0.007	Yes
10. PTH <1.58 pmol/L 6 hrs postoperatively	55	<0.001	Yes

Table 3 Predictive score to assess the risk of postoperative hypocalcemia after total thyroidectomy (CaReBe'S TiP)

Variables		Yes	No
Total serum calcium <9 mg/dL preoperatively (Calcium)	Ca	1	0
Ultrasound image of retrosternal goiter (Retrosternal goiter)	Re	1	0
Bethesda ≥ 4 based on FNA	Be	1	0
Large thyroid gland according to ultrasound (Size)	'S	1	0
Hyperthyroid/Hypothyroid patient in the initial diagnosis (TSH)	Ti	1	0
PTH <1.58 pmol/L 6 hrs after the operation (PTH)	P	1	0
Overall	CaReBe'S TiP	7	0

100% and the specificity is 79.16%. Respectively, when the score has a value ≥ 4 , the sensitivity is 83.3% and the specificity is 100%. (Table 4)

PTH is considered to be the best predictor for the under study complication by many.¹⁵ For this reason, the predictive indicators of CaReBe'S TiP score were compared with those of PTH alone. CaReBe'S TiP score appears to be a better predictive test. This is also illustrated in the figure below where the respective ROC curves are compared (Figure 1).

Discussion

It is estimated that the predictive score developed may have a significant prognostic value regarding the risk of postoperative biochemical hypocalcemia following total thyroidectomy without central neck dissection. At

a scoring value ≥ 3 , the sensitivity is 100%, so it has detected all the patients, who had the complication. At the same time, the NPV is 100% and the PPV of 70.58%, which means that patients with scoring values ranging from 0 to 2 did not suffer from biochemical hypocalcemia, which was 70.58% likely to occur in patients with a scoring value from 3 to 6. However, the specificity in the above scoring value is 79.16%, so there were also detected 20.84% patients without hypocalcemia, who essentially had a false-positive result. Respectively, at a value ≥ 4 , the sensitivity is 83.3% and the specificity 100%. The high specificity means that a positive result in the score will only identify patients who postoperatively have biochemical hypocalcemia. However, some of them will not be detected because of the lower sensitivity.

Table 4 Evaluation of predictive power of CaReBe'S TiP score

Score	Group A, n=24 (Patients without hypocalcemia)	Group B, n=12 (Patients with hypocalcemia)	Sens.	Spec.	PPV	NPV
≥ 3	5	12	100%	79.16%	70.58%	100%
≥ 4	0	10	83.3%	95.83%	90.9%	92%

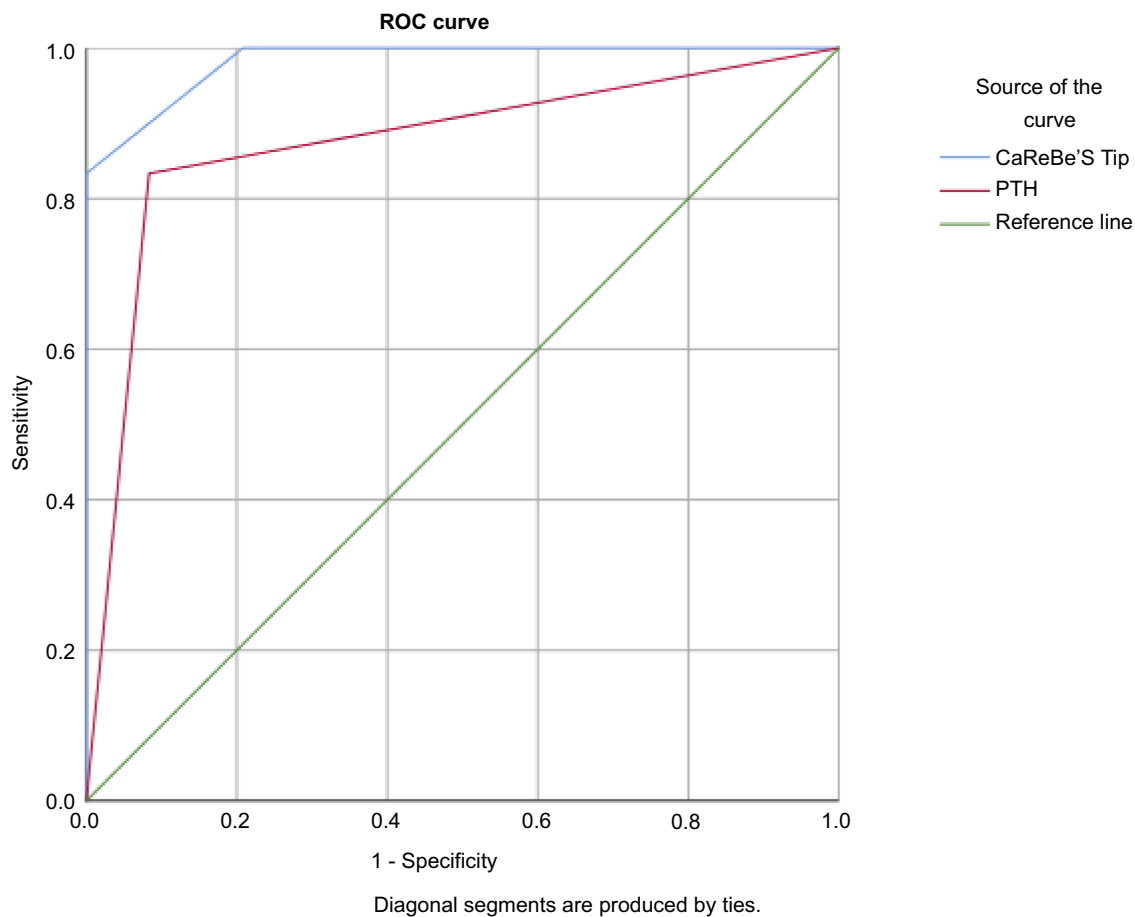

Figure 1 Comparison between the ROC curves of CaReBe'S Tip score and PTH.

Therefore, it is considered that the more acceptable scoring value is ≥ 3 as a screening test. In this way, the two main objectives are achieved. First, all patients who would experience postoperative hypocalcemia could be identified. A prophylactic treatment, including oral calcium supplementation with or without calcitriol, should be administered to them as soon as possible. A few false-positive results are inevitable. The prophylactic medication would also be received from these patients. It should be noted that this treatment has few potential side effects, which are reversed quickly after termination of the medication.¹⁶ Second, patients with a scoring value < 3 would not have biochemical hypocalcemia. Therefore, they should be excluded from prophylactic treatment. Consequently, a more targeted therapeutic approach could be achieved.

A further predictive score with 8 prognostic factors for the same purpose in the international bibliography has been published by Ashim Sarkar et al.¹⁷ The sample of patients is approximately the same, and similar statistical

methods are used. One fundamental difference of the above study is that this was prospective that adds more credibility to the data collected. On the other hand, the scoring value with the highest sensitivity is combined with much lower specificity than those demonstrated in the current study. Also, the postoperative calcium 12 hrs after surgery has been chosen as a predictive factor by Sarkar et al, making the prognostic test less timely. Finally, another limitation of the above research is the predictive factor concerning the excised parathyroid glands, since it is indicative of prophylactic treatment for hypocalcemia.⁹

In conclusion, CaReBe'S TiP predictive score could be applied to the clinical practice to check its reliability and validity, given that it is not detrimental to any patient. However, it would be preferable to initiate a new prospective research by studying the same risk factors. In addition, the risk factor surgeon should be always taken seriously into account, which could not be included in the current study.¹⁸ Also, it is necessary for a larger sample of patients in order to be more representative of the

population and to develop a multivariable logarithmic regression model. In this way, it is likely to create a much more reliable predictive score that could be used effectively as a screening test. It is therefore essential to carry out further research to obtain more accurate and valid results.
