

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

LSPCs to nonapoptotic, iron-dependent cell death via ferroptosis. Indeed, ferroptosis inhibition functionally rescued Aldh3A2 loss. Conversely, genetic and pharmacologic inhibition of ferroptosis inhibitory glutathione peroxidase 4 (GPX4) and cytotoxic therapy triggered increased elimination of Aldh3a2-deficient LSPCs and extended AML-free survival in vivo compared with aberrant stem cells expressing the detoxifying enzyme. This finding provides further evidence that AML relies on increased metabolic plasticity, particularly enhanced FA metabolism, for desensitizing leukemic clones to cell death⁹; it also underscores that distinct metabolic adaptations are likely at play in LSPCs and AML blast cells as suggested by Jordan and colleagues.¹⁰

Future studies are needed to continue identifying LSPC-specific metabolic adaptations and vulnerabilities, particularly in the context of therapeutic interventions for AML. It will also be of critical importance to gain insights into the role of metabolic dependencies in pre-LSPCs, as they are not only the cellular source of primary disease initiation, but they provide a pool of highly transformation-susceptible cells during antileukemic therapy.^{3,4}

PLATELETS AND THROMBOPOIESIS

Comment on Manne et al, page 1317, and Hottz et al, page 1330

COVID-19 concerns aggregate around platelets

Elisabeth M. Battinelli | Brigham and Women's Hospital; Harvard Medical School

In this issue of *Blood*, articles by Manne et al and Hottz et al highlight platelet hyperactivity in COVID-19-associated pathophysiology.^{1,2} Although the hallmarks of COVID-19 include a brisk inflammatory response and respiratory symptoms, the hematologic manifestations of this infection have also garnered attention, with thrombotic complications taking center stage.^{3,4} COVID-19-associated coagulopathy has been characterized by an elevated D-dimer, mild thrombocytopenia, and a prolongation of the activated partial thromboplastin time.⁵ Alongside these laboratory abnormalities, patients present with increased rates of thrombosis.⁶ The role of platelets in the thrombotic complications of COVID-19 is explored in these 2 articles, establishing that platelet hyperactivity contributes to the coagulopathy seen in COVID-19.

Mounting evidence has demonstrated the far-reaching influence of the platelet beyond mediating hemostasis. Platelets are increasingly recognized as key players in facilitating inflammation. The importance of the platelet in viral infection-mediated thrombosis has been established previously.⁷ Endothelial damage, a cornerstone of COVID-19 disease, releases key platelet agonists that send platelets into overdrive.⁸ Inflammation may be exacerbated in patients with hypertension, cardiovascular disease, and obesity, all of which are associated with baseline platelet hyperreactivity.⁹ Interestingly, studies have shown that patients with these underlying comorbidities suffer more severe COVID-19 complications and have a worse outcome.¹⁰ Understanding the role of the platelet in COVID-19 remains elusive. Because the platelet itself does not express the receptor for SARS-CoV-2 binding (ACE2), more remains to be understood about how the virus interacts with platelets and impacts their function.

Propelling the platelet further into the spotlight has been recent evidence demonstrating that megakaryocytes, the precursor cells of the platelet, are present in pulmonary and cardiac tissue from autopsies of patients who have succumbed to COVID-19.¹¹ It remains unclear whether these megakaryocytes in satellite locations contribute to platelet production. Surprisingly, although COVID-19 is associated with severe inflammation, reactive thrombocytosis has not been demonstrated in infected patients. On the contrary, a mild thrombocytopenia is often present, and a decrease in platelet count has been associated with a poor prognosis.¹²

In the first of 2 linked articles, Manne and colleagues demonstrate changes in platelet gene expression and function in COVID-19 patients.¹ Using platelet RNA sequencing, the investigators profile gene expression in the platelets of COVID-19 patients and find altered gene expression profiles in pathways associated with

Schematic cross-section of a blood vessel depicting COVID-19–associated endothelial damage (left panel). At the site of endothelial injury, platelets become activated and aggregate (middle panel). These hyperactive platelets activate monocytes, leading to release of tissue factor, the principle regulator of the coagulation cascade (right panel). RBC, red blood cell.

ubiquitination, antigen presentation, and mitochondrial dysfunction. Patients with COVID-19 have higher levels of platelet activation at rest and increased interactions with neutrophils, monocytes, and T cells compared with healthy donors (see figure). Platelet functionality studies demonstrate hyperactivity, as evidenced by increased aggregation, spreading on fibrinogen and collagen through upregulation of the MAPK pathway, and increased thromboxane generation. Therefore, the investigators extrapolate that hyperactivity of platelets plays a role in the immune-mediated thrombotic manifestations seen in patients with COVID-19. What remains to be determined is whether these platelet gene transcript differences and enhanced platelet functionality are uniquely associated with exposure to COVID-19 or whether other similarly inflammatory conditions also reveal comparable changes. Comparisons with other viral illnesses associated with acute respiratory distress syndrome would be helpful in identifying the exclusivity of these platelet manifestations in COVID-19.

In the second article, Hottz and colleagues again demonstrate that COVID-19 is associated with increased platelet activation. They show that the platelets of critically ill COVID-19 intensive care unit (ICU) patients exhibit increased platelet aggregation and platelet-monocyte aggregation compared with patients with mild COVID-19 infection (see figure). These findings are associated with the characteristic coagulation laboratory changes found in patients with COVID-19, including elevated fibrinogen and D-dimer. Further, these changes correlate with a worse

outcome, with increased need for invasive mechanical ventilation and increased mortality in those with hyperactive platelets. In this study, changes in platelet activation were associated with increased platelet expression of P-selectin and CD63 in patients with more severe disease in comparison with those with mild manifestations. Platelets from patients with severe COVID-19 infection induce monocyte-derived tissue factor (TF) expression that is diminished by pretreating COVID-19 patient platelets with an anti-P-selectin neutralizing antibody or the clinically approved anti- α IIb/ β 3 monoclonal antibody, abciximab. Together, these findings again demonstrate the role of the platelet in COVID-19, linking changes in platelet activation and platelet-dependent monocyte TF expression with disease severity and mortality. Linking platelet-mediated monocyte TF expression to unbridled coagulation and thrombosis remains to be determined.

Although both of these articles clearly demonstrate differences in platelets and platelet function in patients with COVID-19, a well-defined connection between platelet hyperactivity and the coagulopathy seen in COVID-19 patients has not been confirmed. Dedicated studies comparing platelet function testing in COVID-19 patients with and without thrombosis have not been performed. Because platelets are already known to be hyperactive in the setting of inflammation, linking platelet abnormalities directly to thrombotic risk is key to understanding whether the platelet is merely a bystander in the inflammatory milieu or a key pathological regulator of thrombosis in COVID-19.

An understanding of the role of the platelet in COVID-19–associated thrombosis has clear clinical implications in considering antiplatelet therapies for treating COVID-19 patients. The addition of antiplatelet therapy to patient management was addressed in both articles. In the study by Manne et al, platelet hyperreactivity in COVID-19 ICU patients was reduced by pretreatment of the platelets with high doses of aspirin. In the Hottz et al study, platelet-targeting agents, including aspirin and clopidogrel, did not prevent platelet-induced TF in monocytes, yet anti-P-selectin neutralizing antibodies and integrin targeting through abciximab disrupted platelet signaling to monocytes. These findings would suggest that directed blockade of platelet P-selectin and/or other key platelet-activation pathways may interfere with the platelet hyperreactivity observed in COVID-19. Because a modest rate of bleeding and thrombocytopenia have also been reported in COVID-19 patients, overall hemostasis must be considered before instituting antiplatelet therapies.¹³ The work of Manne et al and Hottz et al sets the stage for clinical trials evaluating the efficacy of antiplatelet drugs in COVID-19–associated coagulopathy.

TRANSFUSION MEDICINE

Comment on Grebe et al, page 1359, and Custer et al, page 1351

ART and science of keeping HIV out of the blood supply

Richard Kaufman | Brigham and Women's Hospital

In this issue of *Blood*, Grebe et al¹ report that changing the US blood donation policy for men who have sex with men (MSM) from an indefinite deferral to a deferral of 12 months from last sex did not significantly increase the risk of transfusion-transmitted HIV. In an accompanying article, Custer et al² demonstrate that HIV-positive individuals on antiretroviral therapy (ART) and individuals taking HIV preexposure prophylaxis (PrEP) are donating blood, potentially increasing the risk of transfusion-transmitted HIV.

In developed countries, blood centers protect the safety of the blood supply by deferring high-risk donors and screening all donations for HIV and other pathogens using exquisitely sensitive and specific assays. This multilayered approach has been highly successful. In the United States and many other countries, the per-unit risk of HIV transfusion-transmission is <1 per million.³ However, medical policies and practices continue to evolve, and so do the risks of transfusion-transmitted infection. In this issue of *Blood*, Custer and colleagues report 2 important studies about current risks of transfusion-transmitted HIV. One of these studies is reassuring¹; the other is not.²

HIV antibodies become detectable in blood ~21 days after infection. HIV nucleic acid testing (NAT) turns positive earlier, ~9 to 10 days after infection. Thus, HIV NAT is considered to have a window period of ~9 days (see figure). For donor screening, HIV NAT is typically performed on mini-pools (samples from, eg, 16 donors). If a pool tests positive, the individual samples are tested to identify the HIV-positive donation. Window period donations represent almost all of the residual risk of HIV transfusion-transmission. In these rare cases, an individual donates soon after getting infected with HIV, when the viral RNA load is still very low and before specific

antibody is detectable. The screening tests result as negative, and the donated unit may infect a transfusion recipient.

Policies on donor eligibility, reflected in the predonation Donor History Questionnaire, are intended to prevent individuals with high-risk behaviors from donating in the window period. These policies are often viewed as discriminatory by gay communities; regulators such as the Food and Drug Administration (FDA) try to balance protecting the blood supply with making donation as widely available as possible. In 2000, Australia became the first nation to make MSM a 12-month donor deferral instead of an indefinite deferral. Other countries followed suit, including the United States in 2015.⁴ In April 2020, the FDA reduced the deferral period for MSM to 3 months from last sex,⁵ consistent with policies elsewhere. Intuitively, adopting a 12- or 3-month MSM deferral period should not increase the risk of HIV-contaminated units entering the blood supply given a window period of only 9 days.

However, policy changes can have unintended consequences. Grebe et al decided to examine whether the switch in the United States from an indefinite deferral to a 12-month deferral led to an increase in higher-risk individuals donating blood and a corresponding increase in the risk of transfusion-transmitted HIV. Using data from several US blood centers, the investigators measured the HIV incidence in first-time blood donors before and after the switch to a 12-month MSM deferral. The incidence of HIV in first-time donors was 2.62/10⁵ person-years at baseline and 2.85/10⁵ person-years after the 12-month deferral was implemented

HIV window period. Following HIV infection, HIV RNA becomes detectable by standard NAT after ~9 to 10 days (green). HIV antibody is detectable by immunoassay after ~21 days (red). Blood donations made in the HIV NAT window period are responsible for most of the residual risk of transfusion-transmitted HIV. Adapted from Busch¹⁰ with permission from the author and publisher.
