Letter to the Editor

Characteristics of SARS-CoV-2 super-spreaders in Japan

Dear Editor,

In this Journal, Majra and colleagues reviewed the role of 'super-spreaders' in the COVID-19 pandemic[1]. Since the time of the SARS-CoV epidemic in 2003 and the MERS-CoV epidemic in 2012, it was found that not all patients were equally infectious; super-spreaders were highly contagious to their surroundings and could transmit the infection[2]. Based on the experience of these two epidemics, a super-spreader can be defined as a patient who has a high viral load, sheds virus for a long period of time, and is not necessarily critically ill[3]. In the Covid-19 pandemic, it has also been noted that high viral load leads to high infectivity[4,5], and that the presence of super-spreaders is involved in super-spreading events, where some individuals spread to a disproportionate number of individuals, compared to most individuals who infected only a few or none[3,6]. It has also been reported that patients with severe disease have higher viral load and longer viral shedding period compared to patients with mild disease[7]. However, few studies have examined the characteristics of people with high copy number, taking into account the fact that viral load changes over time. To that end, we conducted a single-center, retrospective study in patients diagnosed with COVID-19 and had their PCR copy number measured multiple times (Supplementary materials 1). Between March 2020 and June 2021, patients with a confirmed diagnosis of COVID-19, admitted to Tokyo Medical and Dental University, with polymerase chain reaction (PCR) copy number measured one or more times (median tested times: 2, range 1–26), were included in the study. A total of 379 patients were eligible for the study.

Table 1 shows the demographic data of the patients. The median age of the patients was 59 years, and about 33% were female. Median number of PCR tests was 2 (range: 1–26). In more than 90% of the patients who had more than one PCR test performed, the viral load was its maximum for that individual at the first or second test. About 59% had underlying disease and about 21% had more than three underlying diseases. Underlying diseases included hypertension (146, 38.5%), diabetes mellitus (82, 21.6%), dyslipidemia (70, 18.5%), hyperuricemia (29, 7.7%), rheumatoid arthritis (8, 2.1%), cancer (71, 18.7%), chronic kidney disease (25, 6.6%), stroke (19, 5.0%), heart disease (including myocardial infarction, atrial fibrillation, chronic heart disease, 34, 9.0%), and lung disease (including asthma and chronic obstructive lung disease, 41, 10.8%). All but one patient in this study were unvaccinated.

Table 2 shows the results of multivariate regression analysis between patient characteristics and log-transformed copy number. It was found that patients with diabetes mellitus, rheumatoid arthritis and history of stroke were significantly more likely to have a higher copy number of log of SARS-CoV-2 (coefficient: 1.25 (95% confidence interval (CI): 0.16–2.35), 3.22 (95% CI: 0.14–6.31), and 2.37 (95% CI: 0.34–4.41), respectively). Patients who had three or more underlying diseases were also significantly associated with increased copy number (coefficient: 1.83: (95% CI: 0.45–3.20)) than those without underlying diseases. After adjustment for gender, age, and smoking status, the associations with having three or more diseases, diabetes mellitus, rheumatoid arthritis, and stroke remained statistically significant (model 2). Detailed discussion is presented in Supplementary materials 2.

This study has several limitations. First, some of the patients included in the analysis were transferred from other hospitals, and it is possible that the copy number of the virus was modified by the treatment before the transfer. Second, the patients we analyzed were moderately to severely ill, and the association of viral load with underlying disease in patients with mild disease is not clear. Third, since the study period was between April 2020 and July 2021, few patients with the Delta variant carrying the L452R mutation were included. Hence, we do not know whether the difference in strains modified the association between the risk factors that were studied and the viral copy number.

There are several study strengths. First, we have conducted multiple PCR tests over time and have examined the association between possible risk factors and viral copy number using the maximum value, considering that viral load changes over time. Second, in our study, specimens for PCR testing were collected from the nasopharynx by a limited number of medical doctors, so the quality of the specimens was maintained. Third, the duration of the study was longer than one year and the number of patients included was larger than that of previous studies[8,7,9].

Clinical implications can be drawn as follows. First, in SARS-CoV-2 infections, it has been reported that infections could occur from super-spreaders who were highly contagious to their surroundings. Thus, our finding will provide useful information for identifying super-spreaders using information on underlying diseases and laboratory data at the time of admission. For example, by identifying potential super-spreaders based on the information, physician could isolate patients in private rooms and elicit the attention of medical personnel to prevent nosocomial cluster outbreaks[10,1] . Second, among patients who underwent multiple PCR tests, more than 90% had reached maximum viral load on the first or second test. This suggests that special infection control measures, such as isolation and alerting healthcare workers, need to be taken especially during the early stages, for patients who are thought to be at high risk of higher viral copy numbers based on the information on underlying diseases and laboratory data at the time of admission.

In moderately to severely ill COVID-19 hospitalized patients, diabetes mellitus, rheumatoid arthritis stroke, and a history of having three or more disease were associated with higher viral load, even after adjusting for age and gender. Lower platelet

	Past	102 (26.9%)
Vaccination status	Not at all	378 (99.7%)
	Once	1 (0.26%)

*1: Patients with only one test were excluded.
*2: Heart disease includes myocardial infarction, chronic heart failure, or atrial fibrillation.
*3: Lung disease includes asthma, chronic obstructive pulmonary disease.

count and lower CRP levels on admission were also associated with higher viral load (Supplementary Table 1). Our study showed possible characteristics of super-spreaders. More research is needed to address the prevention of secondary infections caused by super-spreaders.
