

Cranial and Spinal Oligodendrogliomatosis: A Case Report and Review of the Literature

Abstract

Secondary leptomeningeal gliomatosis is a condition known as a result of invasion of the subarachnoid space or the ventricular system of primary intraparenchymal glioma. In this article, we present a 7-year-old boy presented with neck and back deformity and deterioration of gait. Cranial and spinal magnetic resonance imaging revealed lesions in the supratentorial and infratentorial areas, in the brainstem downward the spinal cord. Disseminated oligodendrogliomatosis is extremely rare and our case we present is the 24th in the literature.

Keywords: *1p19q deletion, leptomeningeal dissemination, oligodendrogliomatosis*

Introduction

Primary oligodendrogliomatosis is a rare entity involving intracranial and spinal leptomeninges without parenchymal focus with a poor prognosis. Secondary oligodendrogliomatosis is the dissemination of a primary parenchymal oligodendroglioma in leptomeninges via subarachnoid space or ventricular system. Early diagnosis is important for early initiation of radiotherapy/chemotherapy that will improve the patient's quality of life and contribute to long-term surveillance. In this article, we report a 7-year-old boy presented with deformity in his back and neck and gait disturbance that magnetic resonance imaging (MRI) demonstrates multiple hyperintense small cystic lesions predominantly in the infratentorial region and an intramedullary expansile contrast-enhanced lesion extending from T5 to T7 level.

Case Report

A 7-year-old boy was evaluated with a complaint of deformity in his back and neck which was noticed 2 months ago and worsening of walking. He was neurologically intact except spasticity in both lower extremities and hyperactivity in deep tendon reflexes. Routine laboratory values were normal. MRI revealed extra-axial multiple cystic lesions in both cerebellar

hemispheres and vermis and cerebellar peduncles, in brainstem most prominently in the periaqueductal area extending to the interpeduncular cistern, and in the hippocampus and parahippocampal area, 4 mm diameter nodular lesion on the posterior wall of the fourth ventricle, communicating hydrocephalus. Cystic lesions in the posterior fossa were also observed extensively along the spinal cord at the cervical, thoracic, and lumbar levels [Figure 1]. The patient was radiologically hydrocephalic but had no symptoms due to increased intracranial pressure. In addition, in T2-weighted images heterogeneous and hyperintense and contrast enhanced in T1-weighted MRI images, an intramedullary expansile lesion was observed extending from lower T5 to lower T7 level [Figure 2]. Baclofen was administered orally 3 × 5 mg for spasticity in lower extremities with the recommendation of pediatric neurology clinic and started on prophylactic anticonvulsant therapy with levetiracetam. Informed consent was received from the family and the patient underwent T6–7 laminoplasty, biopsy from the dural lesion, and duraplasty. Intraoperative somatosensory-evoked potential changes with amplitude reduction did not allow us to go beyond biopsy and more tumor removal. There was no postoperative additional neurological deficit.

Figure 1: (a and c) T2 fluid-attenuated inversion recovery axial image shows multiple hyperintense cystic lesions in the cerebellum and cervical spine. (b) T1-weighted postcontrast image shows a nodular lesion on the posterior wall of fourth ventricle

Pathological result of the patient was reported as a diffuse leptomeningeal glioneuronal tumor [Figure 3]. The tumor cells were characterized by round-to-oval nuclei with finely granular dispersed chromatin, inconspicuous nucleoli with clear oligodendrocyte-like features with perinuclear haloes. No necrosis or endothelial vascular proliferation was observed in the tumor. Focal myxoid change and 1 mitosis per 10 HPF were detected. The neoplastic cells were diffusely immunopositive for S100 and SYNP and immunonegative for GFAP. No ATX loss was detected and IDH1 and p53 were negative. Ki67 proliferation index was 5%–7%. Fluorescence *in situ* hybridization analysis revealed deletion of 1p, whereas 19q was intact. The patient was referred to the pediatric oncology clinic for chemotherapy and radiation therapy. However, the parents preferred to take these treatments in other institutes.

Discussion

Primary diffuse leptomeningeal gliomatosis is pathologically available in two types: primary leptomeningeal astrocytoma and primary leptomeningeal oligodendroglioma. In the literature, primary oligodendrogliomatosis cases have been reported which Michotte *et al.* have compiled in their own study.^[1] Secondary oligodendrogliomatosis is the dissemination of a primary glial tumor by subarachnoid space or ventricular system. In addition to leptomeningeal lesions, intraparenchymal lesions can be seen. In this article, we present a case with cranial and fourth ventricular lesions involved the spinal cord. There are very few reported studies of secondary oligodendrogliomatosis in the literature. There were a total of 24 cases with a current patient, of which 10 were adults and 14 were children [Table 1]. Sudden death was seen in at least three of these cases.^[4,13,18] Only three patients have been reported that lived 5 years or more.^[10,11,14] Only two patients had 1p

Figure 2: (a) Leptomeningeal contrast enhancement at the conus. (b) Sagittal contrast-enhanced T1-weighted image shows intramedullary lesion at T5–7 level. (c) T2 fluid-attenuated inversion recovery axial image shows hydrocephalus

19q deletion, 8 years and more of surveillance was reported in these cases, 1p deletion was observed in our case, but 19q deletion was not seen.^[1,14]

Oligodendrogliomatosis may be difficult to diagnose because it presents with progressive pial enhancement or various symptoms such as hydrocephalus and nonspecific imaging findings. Most patients with oligodendrogliomatosis present with neurological symptoms ranging from headache, nausea, and vomiting to sensory and motor disorders.^[10,13,16,17]

Since it is a rare disease, optimal treatment is controversial. To confirm the pathological diagnosis is the main purpose. Only partial resection was documented in all reported cases. In selected cases, neurosurgical intervention may be necessary for related findings such as hydrocephalus. Chemotherapy and craniospinal irradiation revealed good results. Bourne *et al.* reported stable disease after chemotherapy with cisplatin, vincristine, cyclophosphamide, and etoposide.^[15] Franceschi *et al.* recently announced the treatment with temozolomide.^[20] In general, the prognosis of this disease is poor. However, a higher quality of life has been reported following palliative treatment.

Conclusion

We reviewed the literature for oligodendrogliomatosis for treatment and management options in pediatric age that is a very rare disease that patients may present differently. We present a case who underwent surgery for a biopsy. After pathological diagnosis, chemotherapy and radiotherapy were started for the case that proven to prolong survival.
