#### Abstract

Population aging is creating critical issues in Taiwan, and adults are being forced to maintain productivity at work; in other words, they need to work longer. Therefore, their fitness and health warrant immediate attention. Although the association between health and anthropometric characteristics has been reported, few profiles on Taiwanese adults can be found. The purpose of this study was to provide a suitable reference on the anthropometric data of Taiwanese adults. We recruited 60,056 anthropometric measurements from a representative database. Significant differences were found in every measurement for each gender and age group. Statistically, our results indicated anthropometric differences in different ages. However, CVs showed that the dispersions are minor. This study presents a sufficient profile on Taiwanese adults from a representative database to practitioners and other potential users.

Keywords: obesity; BMI; WHR; Taiwan

## 1. Introduction

Taiwan has been reported as a super-aged society with a rapidly decreasing adult population [1]. In Taiwan, population aging is creating socioeconomic problems, and its impacts worldwide warrant immediate attention. For example, many countries have adopted pension systems to maintain sustainability [2-5]. Moreover, the increasing costs of public health services have also challenged society and its general productivity [6]. Thus, the health condition of adults has become more critical in Taiwan since they are responsible for the productivity of society.

Anthropometric parameters are commonly related to one's physical fitness [7], dietary status [8], lifestyle [9] and general health condition [10,11]. Although anthropometric parameters may be affected by genetic differences, environmental issues and sociocultural conditions, they can still provide significant information on clinical and epidemiological issues [12]. A recent study reported a longitudinal relationship between anthropometric parameters and stress and its tendency to cause overeating [13]. Over the past years, studies have focused on the associations between anthropometric parameters and potential employee selection [14], psychological issues [13], ergonomic product design [15,16] and touchscreen information system design [17]. Even though there are many more indicators that predict human health, anthropometric parameters, such as the body mass index (BMI)
and waist-hip ratio (WHR), provide an easy and inexpensive measurement approach for communities [18].

According to the World Health Organization (WHO), anthropometric data should be collected regularly and provided as a standard reference for preliminary health monitoring [19]. These data are recommended to be shown in 10-year clusters and should be distinguished from gender differences [18-20]. However, to the best of our knowledge, anthropometric reference data have seldom been provided for adults in Taiwan, and previous studies have focused on adolescents [21] and the elderly [22].

In addition, these studies used a small sample for analysis. Increasing the quality of these data is essential. Even though these data may make a limited contribution to scientific development, sufficient reference data are worth to be established due to their practical value, especially for the adult population. Therefore, this study aimed to provide genderand age-specific characteristics of anthropometric parameters in Taiwanese adults by using a secondary database.

## 2. Materials and Methods

### 2.1. Study Design and Participants

Cross-sectional analysis was conducted by using the Taiwanese National Physical Fitness Survey database (NPFSIT). The NPFSIT is operated annually in order to survey the physical fitness level of citizens. The government supervises its procedures, data collection, data management and applications. The design, sampling protocols and data validation of the NPFSIT have been previously introduced [23-25], and de-identified data from the NPFSIT have been released for research. The data that this study has used were collected from 62,586 participants ( 29,685 men, 32,901 women) from October 2014 to March 2015. Convenient sampling was applied at 46 examination stations across 22 cities in Taiwan. The purpose and procedure of the NPFSIT were explained to the participants. All participants provided informed consent. The study design and analysis protocol were supervised by the Institutional Review Board of the Fu Jen Catholic University, Taiwan (FJU-IRB C108006).

### 2.2. Data Collection

Before data collection, some regional training seminars were conducted for the examiners to ensure the protocols and assessments could be correctly presented. All the examiners qualified for the training, as reported previously [26,27]. The study was conducted in three phases. The first was to complete the survey questionnaire. The items included sociodemographic characteristics, lifestyle and perceived health status. The second phase was to check each participant's resting heart rate and blood pressure for safety purposes. Participants whose systolic blood pressure exceeded 140 mmHg or diastolic blood pressure exceeded 90 mmHg or who reported heart disease, hypertension, chest pain, vertigo or musculoskeletal disorders were excluded. The last phase was an anthropometric variable assessment.

The sociodemographic items in the questionnaire were age, gender, education, monthly income and marital status. The lifestyle questions were related to smoking and betel nut chewing. A 5-point Likert scale measured the perceived health status by asking the participants whether they felt healthy. There were three levels of education (elementary school or lower, junior or senior high school and college or higher), monthly income (under 20,000 New Taiwan Dollar (d), 20,001 to 40,000 NTD, and above 40,001 NTD) and marital status (married, never married and divorced/separated/widowed). The participants were also asked whether they never, formerly or currently used cigarettes and/or betel nuts.

### 2.3. Anthropometric Variable Assessment

Anthropometrics were measured for weight, height, waist circumference (WC) and hip circumference (HC). The weight and height were measured by an automatic weight and height machine. The participants were asked to remove their shoes and heavy clothes and stand in a normal posture during measurement. Each WC and HC measurement was
performed twice, and the mean value was calculated. The participants were asked to stand in a normal posture, breathe out and hold their breath for a second, and the WC between the lowest rib and the iliac crest was measured. Similarly, the HC was measured as the distance around the widest part of the buttocks (below the hip plates). The Taiwanese health administration recommends that men maintain their $W C$ below 90 cm and women below 80 cm to avoid obesity [28].

The body mass index (BMI) and waist-hip ratio (WHR) were easily calculated. Based on the BMI, the participants were divided into four different groups: underweight, normal weight, overweight and obese. The cut-off points for four groups were 18.5, 24 and $27 \mathrm{~kg} / \mathrm{m}^{2}$, according to the Health Promotion Administration in Taiwan [29]. The WHR cut-off points were 0.9 for men and 0.85 for women [30].

### 2.4. Statistical Analysis

AS 9.4 software (SAS Institute, Cary, NC, USA) was used to analyze gender- and age-specific data. The statistical measurements included the mean, standard deviation and percentiles (5th, 25th, 50th, 75th, 85th, 90th and 95th). The age groups were 23-24, 25-34, 35-44, 45-54 and 55-64 years. The coefficient of variation (CV) was calculated (standard deviation (SD)/mean) for each anthropometric measurement to determine the dispersion. Means $\pm$ standard deviation (SD) or frequency percentages were presented. Student's $t$-test and chi-square tests were performed for continuous and categorical variables, respectively. Tukey's post hoc test was used to compare the differences among the groups. The level of significance was set at $p<0.05$.

## 3. Results

Table 1 shows the demographics and anthropometrics of the 62,586 participants ( 29,685 men, 32,901 women). Both men and women were significantly different in each measurement (age, body weight, height, BMI, WC, HC, WHR, education, income level, marital status, self-reported health status, smoking status, betel nut chewing; $p<0.001$ ).

Tables 2-5 show the results of each anthropometric parameter (mean, standard deviation, CV and percentile) for both men and women, distributed by age. Significant differences were found in all mean values between genders ( $p<0.05$ ), and all mean values were higher in men than in women. In addition, mean values in both men and women were significantly different among ages ( $p<0.05$ ). In men, the mean WC and WHR in the eldest age group were higher than the younger age groups. In women, except for body weight, all the observed means in the eldest age group were significantly higher than in other groups ( $p<0.05$ ).

The median values (p50) of the body weight and BMI were slightly lower than the means in both men and women. Moreover, the median values of the WC, HC and WHR were slightly lower than the means in women. In general, the result indicated slightly skewed distributions with a wide dispersion for each measurement. Tukey's multiple comparisons test showed that in men, differences in the WHR were significant between all age groups; in addition, significant differences were found in the height, BMI and WC between the eldest (55-64 years) and youngest (23-24 years) age groups ( $p<0.05$; Tables 2 and 3). In contrast, the BMI, WC and WHR in women were significantly different in all age groups. In addition, the means of the body weight, height and HC were significantly different between the eldest and youngest age groups ( $p<0.05$; Tables 4 and 5).

BMI, body mass index; CV, coefficient of variation; SD, standard deviation; $p$ with the ordinal number, percentiles. $a, b, c, d, e$ Superscripts on the mean values represent Tukey's test results. Means with the same letter represent that the mean values of the age groups have no significant difference between/among each other. In contrast, different superscript letters show significant differences ( $p<0.05$ ). * Significant differences in means were found between men and women (Student's $t$-test; $p<0.05$ ). ${ }^{\dagger}$ Significant differences in means were found across all age groups (ANOVA; $p<0.05$ ).

BMI, body mass index; CV, coefficient of variation; SD, standard deviation; $p$ with the ordinal number, percentiles. $\mathrm{a}, \mathrm{b}, \mathrm{c}, \mathrm{d}, \mathrm{e}$ Superscripts on the mean values represent Tukey's test results. Means with the same letter represent that the mean values of the age groups have no significant difference between/among each other. In contrast, different superscript letters show significant differences ( $p<0.05$ ). * Significant differences in means were found between men and women (Student's $t$-test; $p<0.05$ ). ${ }^{\dagger}$ Significant differences in means were found across all age groups (ANOVA; $p<0.05$ ).

The difference in the mean body weight between the youngest (23-24 years) and oldest (55-64 years) age groups was 0.22 kg (median 0 kg ) in men and 2.33 kg (median 3 kg )
in women. Tukey's multiple comparisons test revealed no significant difference between the youngest and oldest age groups. However, the 23-24-year age group was significantly different from all other age groups in men, and the 23-24-year and 25-34-year age groups were significantly different from all the other age groups in women.

The difference in the mean height between the youngest (23-24 years) and oldest ( $55-64$ years) age groups was 6.04 cm (median 6 cm ) in men and 4.85 cm (median 5 cm ) in women. Tukey's multiple comparisons test revealed a significant difference between the three older age groups (35-44, 45-54 and 55-64 years) and the two younger age groups (23-24 and 25-34 years) in both men and women. Moreover, the CVs for height were around 0.03 to 0.04 in both men and women. These results presented even distributions in height in the study population (Tables 2 and 4).

In men, the difference in the mean BMI was $1.64 \mathrm{~kg} / \mathrm{m}^{2}$ (median $1.9 \mathrm{~kg} / \mathrm{m}^{2}$ ) between the youngest (23-24 years) and oldest (55-64 years) age groups. Tukey's multiple comparisons test revealed a significant difference between the two younger age groups (23-24 and $25-34$ years) and the three older age groups ( $35-44,45-54$ and $55-64$ years). In women, the difference in the mean BMI was $2.35 \mathrm{~kg} / \mathrm{m}^{2}$ (median $2.59 \mathrm{~kg} / \mathrm{m}^{2}$ ) between the youngest and the oldest age groups. There were statistically significant differences in all age groups.

The difference in the mean WC between the youngest (23-24 years) and oldest (55-64 years) age groups was 6.86 cm (median 7.4 cm ) in men and 7.61 cm (median 9 cm ) in women. In both men and women, the WC increased with age. Tukey's multiple comparisons test showed a significant difference between the two younger age groups (35-44 and $45-54$ years) and the three older age groups (35-44, 45-54 and 55-64 years). However, there was no significant difference between the 35-44-year and the 45-54-year age group in men (Table 3), while there were significant differences between all the age groups in women (Table 5).

The difference in the mean HC between the youngest (23-24 years) and oldest (55-64 years) age groups was 0.04 cm (median 1 cm ) in men and 1.82 cm (median 2 cm ) in women. The HC increased with age in women. Tukey's multiple comparisons test showed that the 45-54-year age group was significantly different from all other age groups in men, while there were significant differences between all age groups in women (Tables 4 and 5).

The difference in the mean WHR between the youngest (23-24 years) and oldest (55-64 years) age groups was 0.07 cm (median 0.08 cm ) in men and 0.07 cm (median 0.07 cm ) in women. In both men and women, the WHR increased with age. Moreover, there was a significant difference between all age groups in both men and women (Tables 4 and 5)

Table 6 presents the prevalence of BMI categories according to the Taiwanese cutoff points, showing that in both men and women, the normal BMI category was most prevalent (men $40.69 \%$, women $61.72 \%$ ). However, the percentages of overweight and obese individuals combined were larger in men (57.56\%) than in women (32.17\%). Looking at BMI categories by age group, it is clear that in both men and women, the highest percentages of underweight people (men $56.28 \%$, women $15.81 \%$ ) were found in the youngest age group (23-24 years) and the highest percentages of overweight people (men $38.69 \%$, women $28.76 \%$ ) were found in the oldest age group (55-64 years). In addition, the highest percentages of obese people were found in the oldest age group in women ( $16.45 \%$ ) and in the 45-54-year age group in men (25.04\%).

Table 6. BMI in different categories of men and women aged 23 to 64 years.

|  | Age Groups (Years) |  |  |  |  |  |  |  |  |  |  |  |

BMI, body mass index. * Significant differences in means were found across all age groups ( $x^{2}$ test; $p<0.05$ ).
Table 7 shows that men had a higher proportion of a normal WC (71.93\%) than women ( $69.35 \%$ ) but a lower normal WHR ( $69.44 \%$ ) than women ( $76.90 \%$ ). Both men and women in the youngest age group (23-24 years) had the highest percentages of a normal WC (men $84.95 \%$, women $83.74 \%$ ) and WHR (men $89.71 \%$, women $89.01 \%$ ). The oldest age group (55-64 years) had higher percentages of obese people (WC: men $35.01 \%$, women $46.56 \%$; WHR: men $50.56 \%$, women $39.85 \%$ ).

Table 7. WC and WHR in different categories of men and women aged 23 to 64 years.

| Age Groups |  |  |  |  |  |  |  |  |  |  |  |  |

## 4. Discussion

The purpose of the present study was to provide reference data of gender- and agespecific distributions in Taiwanese adults' anthropometric parameters. Results showed significant differences in most anthropometric outcomes (weight, height, BMI, WC, HC and WHR) between genders. More importantly, at the weight level, the prevalence of underweight people was $1.75 \%$ for men and $6.11 \%$ for women, and the prevalence decreased with age. Specifically, there were significant differences in the height, BMI and WC between the youngest and oldest age groups ( $p<0.05$ ) in women. Differences in the WHR were significant between all age groups.

In anthropometric outcomes, results indicated that all indexes (weight, height, BMI, WC, HC and WHR) of men and women were significantly different in each age group. In addition, men are higher means than women, consistent with previous findings. In a previous study [31], all body dimensions were manually measured using digital calipers and measuring tapes in 100 adults and 100 older people, and the results were the same as the present study. In addition, the mean values in both men and women were significantly different in every age group. In men, the mean WC and WHR were higher in the oldest than
the youngest age group. In women, except those for body weight, all the variable means were higher in the oldest age group. This is because aging affects the body composition and metabolism differently between genders, leading to reduced fat oxidation and accumulation of upper-body fat in men and an increased ratio of upper-lower body fat and bone loss in women [32].

WHR results indicated that obesity rates are higher in older people than in the younger population in both men and women. According to the WHO [30], individuals with a higher WHR may have higher abdominal obesity risk. Abdominal obesity is significantly associated with cardiovascular disease [33], risk of cancer [34,35], all-cause mortality [36] and metabolic syndrome [37]. Practitioners should understand that a high WHR could reveal possible health risks for their clients. In addition, promoting a healthier lifestyle could be essential for this population.

On the other hand, although the CVs showed minor dispersions among groups, and the examiners were trained and qualified in the courses, the absolute reliability of the measurements could not be further tested based on the current cross-sectional data. Future studies should be aware of the test reliabilities. For instance, a repeated test may be conducted for the calculation of individual CVs. Thus, the mean CV can be applied to compare the reliability among the measurements [38]. A small mean CV represents a better consistency within each measurement [39].

The strength of the present study was a representative sample from Taiwanese adults. However, there were some limitations. First, the study adopted a cross-sectional design. Thus, no causal relationship could be guaranteed. Future studies should focus on a longitudinal study design to examine sex- and age-related effects on anthropometric development. Second, this study recruited 23-64-year-old Taiwanese adults and cannot be effectively estimated to other populations, such as different ages, races and cultures. Therefore, future studies should survey data from different population groups [40,41] to build a more comprehensive anthropometric profile. Third, as mentioned earlier, although data Heteroscedasticity seemed acceptable by the CV, a measurement error may exist. Lastly, the NPFSIT should widely collect the background of its participants, include more scientific surveys and allow users to connect the data with other sources (e.g., health insurance, medical history) in order to create a better, more comprehensive platform for researchers.

## 5. Conclusions

The anthropometric status provides a preliminary evaluation of one's health and warrants a suitable profile for reference. The present study used a representative population of Taiwanese adults for analysis and provided details of the anthropometric distribution. Even though differences among different ages and genders have been previously reported, the results provide sufficient profiles to practitioners in Taiwan for both clinical and theoretical purposes.

Author Contributions: S.-C.C. drafted the original manuscript. C.-W.L. and P.-F.L. participated in the design and conducted and supervised statistical analyses. H.-L.C. and C.-C.H. critically reviewed and modified the manuscript. All authors have read and agreed to the published version of the manuscript.

Funding: The research was funded by the Taiwan Ministry of Science and Technology (MOST 107-2627-M-030-002) and the Taiwan Ministry of Education (FJU-A0108153).

Institutional Review Board Statement: The study design and analysis protocol were supervised by the Institutional Review Board of the Fu Jen Catholic University, Taiwan (FJU-IRB C108006).
