Abstract

Objectives Discussion of a rare case of angioleiomyoma involving the genuiculate ganglion and the intratemporal facial nerve segment and its surgical treatment.

Design Case report.

Setting Presence of an expansive lesion englobing the genuiculate ganglion without any lesion to the cerebellopontine angle.

Participants A 45-year-old man with a grade III facial paralysis according to the House-Brackmann scale of evaluation.

Main Outcomes Measure Surgical pathology, radiologic appearance, histological features, and postoperative facial function.

Results Removal of the entire lesion was achieved, preserving the anatomic integrity of the nerve; no nerve graft was necessary. Postoperative histology and immunohistochemical studies revealed features indicative of solid vascular leiomyoma.

Conclusion Angioleiomyoma should be considered in the differential diagnosis of genuiculate ganglion lesions. Optimal postoperative facial function is possible only by preserving the anatomical and functional integrity of the facial nerve.

Introduction

Vascular leiomyoma (VL) is an uncommon benign tumor composed of smooth muscle cell and vascular endothelium.¹

Intracranial involvement is quite rare: in fact, only two reports in the literature described an angioleiomyoma involving the cerebellopontine angle (CPA) and internal auditory canal (IAC).^{2,3}

We present the case of a patient with VL localized within the genuiculate ganglion and the initial labyrinthine segment of the facial nerve. To our knowledge, no other VL has been previously described in these sites.

Clinical history, imaging, histological characteristics, and surgical treatment are presented.

Case Report

In August 2012, a 45-year-old man came to our department complaining of a grade III facial paralysis (House-Brackmann scale) that had arisen 5 months earlier.

Otoscopy, as well as pure-tone audiometry, was normal with no tinnitus and no vestibular symptoms. Magnetic resonance imaging (MRI), coronal T1-weighted images revealed a hyperintense, 8-to-10-mm enhancing lesion with contrast englobing the genuiculate ganglion without any alteration of the other cranial nerves. No expansive CPA lesions were present (▶ Fig. 1).

We planned an intact canal wall tympanomastoidectomy (ICWT) with eventual facial nerve grafting. Intraoperatively, we observed a dark red mass encasing the genuiculate ganglion (▶ Fig. 2). We were able to remove the entire lesion, identifying a cleavage plane with the genuiculate ganglion and, thus, preserving the anatomical integrity of the nerve (▶ Fig. 3). The incus was removed during surgery. The ossiculoplasty was immediately performed modeling the incus. Postoperatively, the patient had a mild conductive hearing loss (PTA 25).

Postoperative histology showed cells of medium size with an elongated nucleus and irregular eosinophilic cytoplasm, organized in small bundles. In the context of this lesion,

Fig. 1 Preoperative magnetic resonance imaging, coronal T1-weighted images; the arrowhead indicates 8 to 10 mm hyperintense enhancing lesion with contrast, englobing the geniculate ganglion.

Fig. 2 Intact canal wall tympanomastoidectomy, tumor arising from the geniculate ganglion and the labyrinthine segment of the facial nerve (arrowheads).

Fig. 3 Intact canal wall tympanomastoidectomy, complete removal of the lesion preserving the integrity of the nerve; the arrowhead indicates the imprint of the tumor on the geniculate ganglion.

To our knowledge, our patient is the first case of VL arising within the geniculate ganglion involving the mastoid and tympanic segment of the facial nerve.

Morimoto et al⁵ proposed a classification system that divides VL into three histological subtypes: capillary or solid, cavernous, and venous. Some studies have suggested that the solid subtype is the most frequent in the head and neck region.⁴ Microscopically, VL is generally characterized by a circumscribed nodule with well-organized smooth muscle bundles that extend in fingerlike projections from the smooth muscle in the vessel walls. The cells show eosinophilic cytoplasm and elongated basophilic nuclei with tapered endings (cigar-shaped nuclei).^{1,4,5} Vascular spaces, which are lined by a single layer of endothelial cells, are a constant feature in VL and have an intimate association with neoplastic cells.

numerous vascular spaces were evident with flat endothelium that were compressed by the lesion. Immunohistochemical studies showed abundant positivity of tumor cells for smooth muscle actin and negativity for S100. These aspects were indicative of solid VL (► **Fig. 4**).

At 3-month follow-up the patient was tumor-free with a recovery of the facial palsy to grade II. An MRI performed at this time confirmed the absence of any expansive lesions involving the geniculate ganglion.

Discussion

VL is a benign tumor, with vascular and smooth muscle components, first reported by Stout et al (11 cases) in 1937.¹

VL is rare in the head and neck, Wang et al⁴ in a study published in 2004 analyzed 160 patients with VL affecting these sites; only 21 had a tumor localization in this area. Usually, VL develops in the oral or sinonasal cavities, the parotid, submandibular region, carotid sheath, and retropharynx. Intracranially, it is very rare. Karagama et al² and Pepper et al³ were the first to describe two cases of VL of the IAC and the CPA.

Fig. 4 Geniculate ganglion tumor; the arrowheads indicate the presence of cells with elongated nucleus, eosinophilic cytoplasm organized in small bundles; positivity for smooth muscle actin (immunohistochemical, 10 ×).

Immunohistochemical studies were positive for muscle-specific actin, desmin, and vimentin and negative for S100 protein, CD34, and CD31.³

Histological differential diagnoses include peripheral nerve sheath tumor (neurofibroma and schwannoma) and solitary fibrous tumor.^{1,3}

Computed tomography (CT) or MRI have no specific findings for preoperative diagnosis of VL,⁶ Mass enhancement subsequent to contrast administration, owing to the vascular nature of the lesion, might be characteristic. Therefore, only surgical removal and histological examination make it possible to establish a diagnosis with certainty.

The best treatment strategy for lesions involving the facial nerve has not yet been fully established. A conservative strategy is often adopted in the presence of normal facial nerve function or minimal preoperative dysfunction.⁷ In contrast, others proposed not delaying surgery at all, pointing out the increased risk for hearing loss and the better results of facial reconstruction in those patients having no facial palsy.⁸

When surgical management is selected, the decision regarding the surgical approach to use depends on tumor size and site. When the tumor extends from the geniculate ganglion to the tympanic segment of the nerve, as in our case, the transmastoid extralabyrinthine approach allows access to both these portions and to the beginning of the labyrinthine portion.⁹ Unlike our case, facial nerve integrity may be spared on rare occasions; more frequently, nerve reconstruction is required. Falcioni et al,⁷ in a retrospective case review analyzing 28 patients undergoing surgery for primary facial nerve tumors, preserved the anatomic integrity of the nerve in 4 cases. All the others required a nerve interruption followed by immediate reconstruction using a sural nerve graft. Also, Yamaki et al,¹⁰ in three cases of geniculate neurinoma after removal of the lesion, achieved facial nerve reconstruction with intratemporal anastomosis of the great auricular nerve. They preferred to use the greater

auricular nerve because it can be readily obtained from the neighboring anatomical field.

To conclude, angioleiomyoma should be considered in the differential diagnosis of the geniculate ganglion lesion. Our study showed that every effort should be made to preserve the anatomic and functional integrity of the facial nerve. This strategy seems to ensure the best possible postoperative facial function.¹¹
