This study analyzed whole blood samples ($n = 56$) retrieved from 30 patients at 1 to 21 (median 9) mo after verified COVID-19 to determine the polarity and duration of antigen-specific T cell reactivity against severe acute respiratory syndrome coronavirus 2–derived antigens. Multimeric peptides spanning the entire nucleocapsid protein triggered strikingly synchronous formation of interleukin (IL)-4, IL-12, IL-13, and IL-17 *ex vivo* until ~70 d after confirmed infection, whereafter this reactivity was no longer inducible. In contrast, levels of nucleocapsid-induced IL-2 and interferon- γ remained stable and highly correlated at 3 to 21 mo after infection. Similar cytokine dynamics were observed in unvaccinated, convalescent patients using whole-blood samples stimulated with peptides spanning the N-terminal portion of the spike 1 protein. These results unravel two phases of T cell reactivity following natural COVID-19: an early, synchronous response indicating transient presence of multipolar, antigen-specific T helper (T_H) cells followed by an equally synchronous and durable T_{H1} -like reactivity reflecting long-lasting T cell memory.

SARS-CoV-2 | COVID-19 | T cell cytokines | longevity | T helper cells

After encountering antigen, naïve $CD4^+$ T cells follow trajectories into subsets of antigen-specific memory and effector T helper (T_H) cells that may be identified by their patterns of cytokine formation (1). T_{H1} -polarized cells thus generate interleukin (IL)-2 and interferon- γ (IFN- γ) to induce cell-mediated elimination of intracellular pathogens, including viruses (2). T_{H2} cells produce IL-4 and IL-13 that facilitate B cell function and promote tissue repair after infection (3, 4). Additional T_H cell subsets include T_{H17} cells producing IL-17 that attracts neutrophils to infected tissue (5) and T follicular helper (T_{FH}) cells that produce IL-21 to promote B cell function in germinal centers (6). In a parallel pathway, naïve $CD8^+$ T cells differentiate into central memory, effector memory, and effector cells endowed with cytotoxicity against virus-infected cells alongside the ability to generate IL-2 and IFN- γ (7).

This study aimed to determine severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)-specific T cell reactivity in whole-blood samples from healthy volunteers available 1 to 21 mo after recovery from verified COVID-19. We analyzed antigen-specific T_H cell cytokines induced in these blood samples *ex vivo* after exposure to peptides spanning the entire nucleocapsid (NC) protein (amino acids [aa] 1 to 419, 102 peptides) or the N-terminal portion of the spike 1 (S1) protein (aa 1 to 692, 170 peptides).

Results

Transient and Multipolar T_H -Type Reactivity after COVID-19. Whole-blood samples from previously infected patients ($n = 30$) produced IL-4 and IL-13 in response to NC peptides until ~70 d from confirmed COVID-19. Thereafter, these T_{H2} -type cytokines were not inducible over levels in parallel unstimulated samples or in NC peptide-stimulated samples from uninfected controls. The initial T_{H2} -type reactivity occurred concomitantly with a T_{H17} -type response. Levels of NC-induced T_{H2} and T_{H17} cytokines were remarkably correlated in the initial phase after infection with intercytokine Pearson r approaching 1. Similar results were obtained by the addition of multimeric S1 peptides to whole blood recovered from previously infected patients who had not been vaccinated (Fig. 1).

Unexpectedly, IL-12, a prototype mediator of T_{H1} -type immunity (8), was induced by NC and S1 peptides synchronously with IL-4, IL-13, and IL-17 in the first months after infection (Fig. 1). The stark correlation between antigen-induced levels of these early-phase cytokines suggests that IL-4, IL-12, IL-13, and IL-17 were generated by the same T cell. In search for a unifying T cell phenotype that may produce these cytokines, we considered T_{FH} cells that transcribe multiple cytokine genes and are induced early after COVID-19 (9). The T_{FH} signature cytokine IL-21 was, however, weakly induced by NC or S1 peptides in whole-blood cultures (induction observed in one of five analyzed samples at <70 d after infection), which argues against IL-21⁺ T_{FH} cells as the source of the observed multipolar cytokine response.

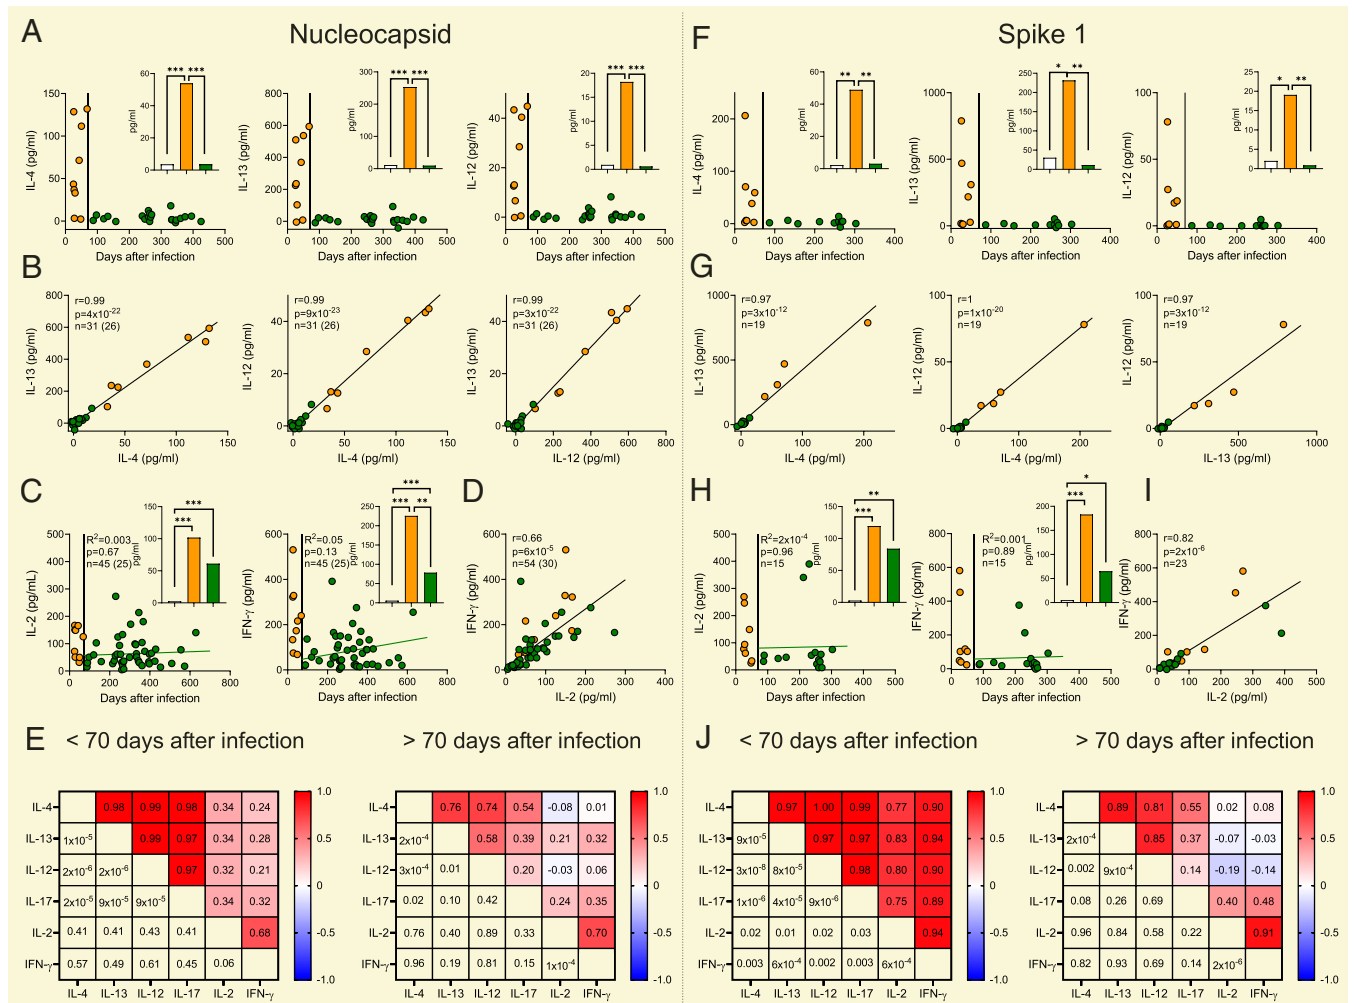

Fig. 1. Two phases of antigen-specific T cell reactivity to SARS-CoV-2-derived peptides after COVID-19. The left (Nucleocapsid) and the right (Spike 1) panels show NC and S1 peptide-induced formation of (A and F) IL-4, IL-12, and IL-13 and (C and H) IL-2 and IFN- γ in whole-blood samples from patients with previously confirmed COVID-19 vs. day after infection. The inset bars show mean levels of induced formation of each cytokine in uninfected controls ($n = 24$ samples from 17 subjects for NC and $n = 11$ for S1, white bars) and convalescent patients sampled early ($n = 9$ samples from 8 subjects for NC and $n = 8$ for S1, orange bars) or late ($n = 22$ samples from 19 subjects [A], $n = 45$ samples from 25 subjects [C] for NC and $n = 11$ [F] and $n = 15$ [H] for S1, green bars) after infection. All data points are shown in each graph. For each donor a mean of all samples within each phase was used for statistical analysis as calculated by permutation. In C and H the green regression lines show NC- and S1-induced cytokines in the late convalescent phase and were estimated using linear mixed-effects models. B, D, G, and I are scatter plots of NC- and S1 peptide-induced formation of (B and G) IL-4, IL-12, and IL-13 and (D and I) IL-2 and IFN- γ in patients with previous COVID-19. The number of observations is indicated by n with the unique number of donors in brackets if serial samples from the same subject were available. All data points are shown in each graph and the regression line was estimated by linear mixed-effects models. A mean of all samples within the early (<70 d after infection) or the late (>70 d after infection) phase from each donor was used to estimate Pearson correlation for unique donors. E and J are a heat maps showing the correlation (Pearson r , above the diagonal) between NC- and S1-induced formation of cytokines in the early (Left) and late (Right) phase after confirmed COVID-19. P values corresponding to each correlation are shown below the diagonal. For each donor a mean of all samples within each phase was used for statistical estimation of correlation. Orange dots show results at early (<70 d) and green dots at later (>70 d) convalescence after infection. * $P < 0.05$, ** $P < 0.01$, **** $P < 0.001$.

Long-Lasting T_H1-Type Immunity. NC- and S1-specific IL-2 and IFN- γ were induced early (<70 d) after confirmed infection and correlated weaker, or not at all, with IL-4, IL-12, IL-13, or IL-17 in the early convalescent phase. However, antigen-induced IL-2 and IFN- γ persisted without discernable waning over time and were strikingly correlated, suggesting that the SARS-CoV-2-specific T cell reactivity observed early and late after COVID-19 derived from separate clones of antigen-specific T cells (Fig. 1).

Discussion

The observed durability of IL-2 and IFN- γ responses imply the existence of long-lasting T cell memory following COVID-19, congruous with recent findings demonstrating presence of virus-reactive CD4⁺ and CD8⁺ memory-type T cells after

infection (10, 11). In previous studies, however, the half-life of T cell memory after COVID-19 was estimated at 3 to 5 mo (10). Our results suggest that IL-2- and IFN- γ -producing T cells reactive with SARS-CoV-2 prevail longer than anticipated from previous reports. However, our results do not exclude that fewer but more efficient antigen-specific T cells contributed IL-2 and IFN- γ in the late convalescence phase.

This study has weaknesses, including a small sample size and an inherently short follow-up after infection. Also, our study did not identify the detailed phenotypes of cytokine-producing T cells. Although IL-4, IL-13, and, in particular, IL-17 responses to antigen are likely reflecting T_H cell function, the finding of highly synchronous formation of IL-12, which is produced mainly by dendritic cells and macrophages (12), implies that antigen-presenting cells may have contributed IL-12 in the first months after COVID-19. The strengths

embrace the identification of two distinct phases of antigen-specific T cell responses among patients recovering from COVID-19. The persistent T_H1-type reactivity is consistent with reports of low incidence of severe COVID-19 in reinfecting patients (13). In particular, the observed long-term T cell reactivity against NC is compatible with the reportedly reduced incidence of reinfection despite the emergence of strains of SARS-CoV-2 carrying mutations in the spike region (14).

Materials and Methods

The study included 81 blood samples from 44 otherwise healthy hospital workers. Ethics approval was granted by the Swedish Ethical Review Authority and by the Swedish Medical Products Agency (for more details, see [SI Appendix, Extended Methods](#)). All participants gave written informed consent before enrollment. Freshly recovered whole-blood samples were stimulated with 15-mer peptides spanning the NC protein (aa 1 to 419, 102 peptides; 130-126-699;

Miltenyi Biotec), the N-terminal portion of the S1 protein (aa 1 to 692, 170 peptides; 130-127-041; Miltenyi Biotec), or were unstimulated as described in ref. 15. Levels of IL-2, IL-4, IL-12, IL-13, IL-17, and IFN- γ were measured in plasma supernatant from whole-blood samples using FirePlex-96 Key Cytokines Immunoassay panel (ab243549 and ab285173; Abcam), and levels of IL-21 in these plasma supernatants were measured by enzyme-linked immunosorbent assay (IL-21 DuoSet ELISA, DY8879-05; R&D Systems). Results are presented as peptide-induced cytokine responses with cytokine levels in unstimulated samples subtracted. Participants, samples, and methods are further described in [SI Appendix, Extended Methods](#). Additional details and deidentified primary data are available in [Dataset S1](#).

Data Availability. All study data are included in the article and/or supporting information.
