Purpose: Obstructive sleep apnea (OSA) is common in hypertrophic cardiomyopathy (HCM) patients and is related to worse adverse prognosis in HCM patients. However, there are no acknowledged warning characteristics to help to identify OSA in HCM patients.

Methods: Seventy-one HCM patients and forty-nine hypertensive (HTN) patients as control group underwent polysomnography (PSG) examination at the Second Affiliated Hospital of Nanchang University from January 2015 to December 2019 patients were consecutively enrolled. The characteristics were analyzed and compared between HCM patients with OSA and without OSA.

Results: A total of 37 (52%) HCM patients and 25 (51%) HTN patients were diagnosed with OSA. High body mass index (BMI) (OR = 1.228, 95% CI: 1.032, 1.461, P = 0.020) and low estimated glomerular filtration rate (eGFR) (OR = 0.959, 95% CI: 0.931, 0.989, P = 0.007) independently correlated with the occurrence of OSA in HCM patients, respectively. Multiplicative interaction was shown between high BMI and low eGFR on the risk of OSA in HCM patients (OR: 6.050, 95% CI: 1.598, 22.905, P = 0.008). The additive interaction analysis further suggested that 70.1% of HCM patients developed OSA due to the additive interaction between BMI and eGFR. The identification ability of OSA in HCM patients was significantly enhanced by using both BMI and eGFR (area under receiver-operating characteristic analysis curve 0.785; P = 0.000038) as compared with BMI (area under curve 0.683, P = 0.008) or eGFR (area under curve 0.700, P = 0.004), respectively.

Conclusion: High BMI or low eGFR independently related to the occurrence of OSA in HCM patients, and the multiplicative and additive interactions between BMI and eGFR increased the identification ability of OSA in HCM patients.

Keywords: hypertrophic cardiomyopathy, obstructive sleep apnea, body mass index, estimation of glomerular filtration rate, biological interaction

Introduction

Hypertrophic cardiomyopathy (HCM) is the most common hereditary cardiomyopathy,¹ and the prevalence is at least 0.2% in populations.^{2,3} Obstructive sleep apnea (OSA) is the most common type of sleep apnea,⁴ which is characterized by partial (hypopnea) or complete (apnea) airway obstruction during sleep despite respiration labored, leading to upper airway structure collapse. HCM has been a known cause of cardiac morbidity and mortality, and OSA is a significant reversible cause of many cardiovascular diseases including hypertension,⁵ myocardial infarction,⁶ atrial fibrillation (AF),⁷ sudden cardiac death (SCD)⁸ and renal disease.⁹ OSA has been seen to occur concurrently in several cardiovascular diseases including heart failure, and indeed in HCM. Since 2004, Banno et al firstly reported that OSA might be a common disease in HCM patients, there have been many clinical studies on the clinical characteristics and incidence of

HCM patients with OSA, suggesting that 32% to 80% HCM patients may have OSA.^{10–15} As a common complication, OSA is known to increase the risk that contributes to morbidity and mortality in HCM including arrhythmias, myocardial hypertrophy, and SCD.¹⁶

Considering the correlation between HCM and OSA, researchers had tried to find predictive indicators to identify the risk of OSA in HCM patients. One study indicated that age larger than 45 years old and the presence of atrial fibrillation helped to identify OSA in HCM patients.¹⁷ Another study showed that male, age, body mass index, hypertension and left ventricular outflow tract obstruction were significantly correlated with OSA in HCM patients.¹⁸ We previously found that HCM patients with OSA had a higher risk of eGFR decline compared with HCM patients without OSA, indicating low eGFR might be a warning characteristic identifying the occurrence of OSA in HCM patients.¹⁹ We therefore investigated the characteristics including eGFR in a cohort of HCM patients to find the potential risk factors and their potential interactions on the occurrence of OSA in HCM patients.

Methods

Patients

We included 71 consecutive patients diagnosed with HCM (no relatives of the index cases were included) and 49 HTN patients as control group at the Second Affiliated Hospital of Nanchang University from January 2015 to December 2019. HTN patients were matched for BMI, sex, age, systolic and diastolic blood pressure by using propensity score matching from the patients admitted to the hospital at the same time as HCM patients. All patients received polysomnography (PSG) and were divided into OSA+ and OSA- according to apnea-hypopnea index (AHI) ≥ 15 or < 15 events/h. OSA was diagnosed according to Chinese Guidelines for the Diagnosis and Treatment of Obstructive Sleep Apnea Hypopnea Syndrome (Revised Edition 2011).²⁰ HCM was diagnosed in accordance with the 2014 ESC Guidelines on the diagnosis and management of HCM.²¹ For patients with hypertension, HCM was diagnosed only when the patients met the following criteria: 1) family history of HCM; 2) maximum LV wall thickness ≥ 15 mm; 3) marked repolarization abnormalities, conduction disease or Q-waves on 12 lead electrocardiogram.²¹

Exclusion criteria were patients who have already received continuous positive airway pressure (CPAP) therapy, central sleep apnea, acute myocardial infarction, acute heart failure, severe respiratory insufficiency, severe liver disease, systemic or local inflammatory, cancer and patients who refused to participate in the study.

The study was approved by the Medical Research Ethics Committee of Second Affiliated Hospital of Nanchang University and a signed informed consent was obtained from each patient before participation. All methods were performed in accordance with the relevant guidelines and regulations. The study was carried out by complying with the Declaration of Helsinki.

Clinical Indices

Doppler echocardiography was used to evaluate the cardiac structure and function as described previously.²² All echocardiographic examinations were performed on a Siemens-Acuson SequoiaTM 512 ultrasound machine (Siemens, Erlangen, Germany) with a curved array multifrequency transducer (2.25–4.25MHz) by experienced sonographers who were blinded to the patients' clinical characteristics. Two-dimensional and two-dimensionally guided M-mode images were recorded from standardized views. Left atrial diameter, right atrial diameter, left ventricular end-diastolic diameter (LVIDd), left ventricular end-diastolic posterior wall thickness (PWTd), right ventricular end-diastolic diameter, inter-ventricular septal wall end-diastolic thickness (SWTd), ascending aorta diameter, left ventricular mass index (LVMI), left ventricular ejection fraction, left ventricular outflow tract obstruction were measured. Left ventricular outflow tract obstruction is defined as an instantaneous peak Doppler LV outflow tract pressure gradient ≥ 30 mm Hg at rest or during physiological provocation such as Valsalva manoeuvre, standing and exercise. LV mass was calculated by the formula: $LV\ mass = 0.8 \times \{1.04[(LVIDd + PWTd + SWTd)^3 - (LVIDd)^3]\} + 0.6\ g$.²³ LVMI was calculated by dividing LV mass by body surface area. The body surface area was calculated as follows: $0.0073 \times (\text{height in centimeter}) + 0.0127 \times (\text{weight in kilogram}) - 0.2106$ (for female), $0.0057 \times (\text{height in centimeter}) + 0.0121 \times (\text{weight in kilogram}) + 0.0882$ (for male).²⁴

All participants underwent overnight PSG (PHILIPS RESPIRONICS, Alice PDx, 1001 Murry Ridge Lane Murrysville, PA 15668). PSG was performed and scored according to the American Academy of Sleep Medicine (AASM) practice standards. An OSA was defined as a drop in airflow to $\leq 90\%$ of baseline for ≥ 10 s as recorded with the oronasal sensor with continued respiratory effort. Apnea was defined as the complete cessation of airflow or a clear decrease in airflow $\geq 90\%$, lasting for ≥ 10 s. Hypopnea was defined as a clear decrease in airflow $\geq 50\%$ lasting for ≥ 10 s accompanied by a decrease in blood oxygen saturation (SpO₂) of at least 3% or a clear decrease in airflow $\geq 30\%$ lasting for ≥ 10 s accompanied by a decrease in SpO₂ of at least 4% and/or associated with arousal. The average number of apneas and hypopneas per hour of sleep was defined as the AHI. Nocturnal oxygen desaturation was assessed as the minimum O₂ saturation during sleep. The diagnosis and severity of OSA were based on the definitions recommended by AASM as follows: non-OSA (AHI < 5), mild OSA ($5 \leq$ AHI < 15), moderate OSA ($15 \leq$ AHI < 30) and severe OSA (AHI \geq 30). Patients with AHI ≥ 15 were recruited in the present study.

eGFR was calculated on the basis of Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI):²⁵ serum creatinine of woman ≤ 62 $\mu\text{mol/L}$: $\text{eGFR} = 144 \times (\text{serum creatinine}/62)^{-0.329} \times (0.993)^{\text{age}}$; serum creatinine of woman > 62 $\mu\text{mol/L}$: $\text{eGFR} = 144 \times (\text{serum creatinine}/62)^{-1.209} \times (0.993)^{\text{age}}$; serum creatinine of man ≤ 80 $\mu\text{mol/L}$: $\text{eGFR} = 141 \times (\text{serum creatinine}/80)^{-0.411} \times (0.993)^{\text{age}}$; serum creatinine of man > 80 $\mu\text{mol/L}$: $\text{eGFR} = 141 \times (\text{serum creatinine}/80)^{-1.209} \times (0.993)^{\text{age}}$.

A standardized medical history and accurate physical examination were obtained from all patients. Smoking status and medications were recorded. Height and weight were measured in a standing position without shoes. Body mass index (BMI) was calculated as weight (kg) divided by height (m) squared. After a 12-h fasting (no alcohol), a peripheral blood sample was collected. Creatinine, uric acid, urea nitrogen, fasting plasma glucose, glycosylated hemoglobin, total cholesterol (TC), triglycerides (TG), high-density lipoprotein (HDL) cholesterol and low-density lipoprotein (LDL) cholesterol were measured with standard assays for all patients. All the biochemical variables were measured using an auto-analyzer (OLYMPUS AU-2700) at the central laboratory of the Second Affiliated Hospital of Nanchang University.

Statistical Analysis

t-test was used for normally distributed results, and the results were expressed as mean \pm standard deviation. Mann-Whitney *U*-test was used for those who did not normally distribute, the result is expressed by quartile spacing. Differences between groups were evaluated using one-way analysis of variance (ANOVA) followed by the post hoc test with Least-Significant difference (LSD) correction, for the continuous variables, and the chi-square test, for the categorical variables, and the results were described by composition ratio. Binary Logistic regression analysis was used to identify the risk factors associated with the occurrence of OSA in HCM. Continuous variables with a skewed distribution were natural logarithm (ln)-transformed to attain normal distributions.

Body mass index (BMI) was stratified into two levels with a boundary of 24 (non-High BMI $< 24 \text{ kg/m}^2$; High BMI $\geq 24 \text{ kg/m}^2$); Estimate glomerular filtration rate (eGFR) was stratified into two levels with a boundary of 90 (non-Low eGFR $\geq 90 \text{ mL/min per } 1.73 \text{ m}^2$; Low eGFR $< 90 \text{ mL/min per } 1.73 \text{ m}^2$). ROC curve was constructed for BMI and eGFR. The area under the curve (AUC), sensitivity, and specificity were calculated to predict the ability to detect the occurrence of OSA in HCM, with an AUC value of 0.50 indicating no accuracy and a value of 1.00 indicating maximal accuracy.

We performed multinomial logistic regression analyses to identify the multiplicative interaction of high BMI and low eGFR on the occurrence of OSA. In multinomial logistic regression analysis, the group without high BMI and low eGFR was used for reference. The crude model was the primary model. The model 1 was adjusted for current smoking, hypertension and atrial fibrillation. The model 2 was adjusted for current smoking, hypertension, atrial fibrillation, fasting plasma glucose, and glycosylated hemoglobin. The model 3 was adjusted for current smoking, hypertension, atrial fibrillation, fasting plasma glucose, glycosylated hemoglobin, total cholesterol, triglyceride, low-density lipoprotein and high-density lipoprotein.

Three measures of biological interaction: the relative excess risk due to interaction (RERI); the attributable proportion due to interaction (AP); and the synergy index (S) were used to evaluate the interaction of high BMI and low eGFR on the occurrence of OSA. If there is no biological interaction, RERI and AP are equal to 0 and S is equal to 1. The biological interaction was accessed by the methods set up by Tomas Andersson.²⁶ Results were adjusted for current

smoking, hypertension, atrial fibrillation, fasting plasma glucose, glycosylated hemoglobin, total cholesterol, triglyceride, low-density lipoprotein and high-density lipoprotein.

A two-sided P value of <0.05 was considered significant. All statistical analyses were performed using SPSS software for Windows, version 21.0 (SPSS, Chicago, IL, USA).

Results

Baseline Characteristics of the Patients

Table 1 details the baseline characteristics of patients. Total 71 consecutive HCM patients and 49 HTN patients were enrolled in this study. OSA was present in 37 patients (52%) with HCM and 25 patients (51%) with HTN. Compared with HCM with OSA group (HCM OSA +) and HTN with OSA group (HTN OSA +), the BMI and systolic blood pressure were significantly lower in HCM without OSA group (HCM OSA -) ($P < 0.05$). AHI was significantly higher in HTN OSA + than that in HCM OSA + ($P < 0.05$). Compared with HCM OSA +, HTN OSA + had a significantly decreased

Table 1 Clinical Characteristics of the Study Groups

Abbreviations: ACE-Is, angiotensin-converting enzyme inhibitors; ARBs, angiotensin II receptor blockers; eGFR, estimate glomerular filtration rate; HDL-C, high-density lipoprotein cholesterol; HCM, hypertrophic cardiomyopathy; LDL-C, low-density lipoprotein cholesterol; OSA, obstructive sleep apnea.

minimum O₂ saturation ($P < 0.05$). Compared with HCM OSA -, the minimum O₂ saturation in HTN without OSA group (HTN OSA -) was also significantly lower ($P < 0.05$). HTN patients administered fewer beta-blockers than HCM patients ($P < 0.001$). HCM OSA + had a significantly higher creatinine and lower eGFR than HCM OSA - ($P < 0.001$); however, no differences of creatinine and eGFR were seen between HTN OSA+ and HTN OSA -. There was no significant difference between the two groups in gender, age, current smoking, diastolic blood pressure, glycosylated hemoglobin, total cholesterol, triglyceride, low-density lipoprotein and high-density lipoprotein.

Echocardiography

Table 2 details the echocardiographic data of the two groups. The HCM with OSA group had significantly wider ascending aorta diameter ($P < 0.05$) than the HCM group. There were no significant differences in left atrial diameter, right atrial diameter, left ventricular end-diastolic diameter, right ventricular end-diastolic diameter, interventricular septal wall end-diastolic thickness, left ventricular end-diastolic posterior wall thickness, left ventricular mass index, left ventricular ejection fraction, and left ventricular outflow tract obstruction between the two groups.

BMI and eGFR Were Independently Associated with the Occurrence of OSA in HCM

Table 3 details the univariate and multivariate logistic regression analyses in the HCM patients with and without OSA. The univariate logistic regression analysis showed that BMI (OR=1.249,95% CI: 1.064, 1.466, $P = 0.006$), SBP (OR=1.028,95% CI: 1.005, 1.052, $P = 0.015$), Ln Creatinine (OR = 16.190, 95% CI: 2.475, 105.917, $P=0.004$), eGFR (OR=0.959,95% CI: 0.934, 0.986, $P=0.003$) were significantly correlated with the occurrence of OSA. Considering the causal relationship between eGFR and creatinine, creatinine values were not included in the multivariate analysis. The multivariate regression analysis further identified that BMI (OR=1.228,95% CI: 1.032,1.461, $P = 0.020$) and eGFR (OR=0.959,95% CI: 0.931,0.989, $P = 0.007$) were independently correlated with the occurrence of OSA.

ROC Analysis for BMI and eGFR to Predict the Occurrence of OSA in HCM Patients

To determine the ability of BMI and eGFR to predict the occurrence of OSA in HCM patients, ROC analysis was performed, and the results are shown in Figure 1 and Table 4. The AUC for BMI and eGFR to predict the occurrence of OSA was 0.683, 0.700, respectively. The highest Youden's index was 0.336, 0.316 respectively and the sensitivity and specificity were 0.865 and 0.471, 0.559 and 0.757, respectively. Then the multivariate logistic regression analysis of BMI and eGFR values was included in the SPSS software to obtain the predicted probability values of both, and then the values were included in the ROC curve analysis. After the combination of BMI and eGFR, the cutoff value was 0.646 which had the maximum value of the Youden's index of 0.507, and the corresponding sensitivity and specificity were 0.595 and 0.912. The AUC was 0.785.

Table 2 Echocardiographic Data of the Study Groups

	HCM OSA+ (n = 37)	HCM OSA- (n=34)	P value
Left atrial diameter, mm	39.51±5.97	40.71±7.42	0.456
Right atrial diameter, mm	36.00 (35.00,39.00)	36.00 (34.00,39.50)	0.698
Left ventricular end-diastolic diameter, mm	45.78 ±7.58	44.97±7.43	0.650
Right ventricular end-diastolic diameter, mm	22.00 (20.00,23.00)	22.00 (18.75,23.25)	0.688
Interventricular septal wall end-diastolic thickness, mm	17.95±4.03	19.35±3.16	0.108
Left ventricular end-diastolic posterior wall thickness, mm	11.00 (10.00,13.00)	12.00 (10.00,14.00)	0.926
Ascending aorta diameter, mm	32.49±4.00	30.50±4.18	0.045
Left ventricular mass index, g/m ²	158.69±64.40	175.36±50.23	0.231
Left ventricular ejection fraction, %	63.11±10.37	62.44±9.23	0.776
Left ventricular outflow tract obstruction, n (%)	17 (45.95%)	16 (47.06%)	0.925

Abbreviations: HCM, hypertrophic cardiomyopathy; OSA, obstructive sleep apnea.

Abbreviations: ACE-Is, angiotensin-converting enzyme inhibitors; ARBs, angiotensin II receptor blockers; CI, confidence interval; DBP, diastolic blood pressure; eGFR, estimated glomerular filtration rate; HDL-C, high-density lipoprotein cholesterol; HCM, hypertrophic cardiomyopathy; LDL-C, low-density lipoprotein cholesterol; LVEF, left ventricular ejection fraction; LVMI, left ventricular mass index; OR, odds ratio; SBP, systolic blood pressure; OSA, obstructive sleep apnea; NYHA, New York Heart Association.

Interaction of BMI and eGFR on the Occurrence of OSA in HCM Patients

Interaction of BMI and eGFR on the occurrence of OSA in HCM patients was assessed both on multiplicative interaction and on additive interaction in the present study. The multiplicative interaction was further identified by multinomial logistic regression analysis (Table 5). Results showed that compared with patients without High BMI and Low eGFR, patients with High BMI (OR: 1.100, 95% CI: 0.192, 6.286, $P = 0.915$) or with Low eGFR (OR: 1.711, 95% CI: 0.403, 7.271, $P = 0.467$) had no significantly increased risk on the occurrence of OSA in HCM patients. However, there was a significantly higher risk of the occurrence of OSA in HCM patients with both high BMI and low eGFR (OR: 6.050, 95% CI: 1.598, 22.905, $P = 0.008$). This effect was persisted after adjusting for different confounders in models 1 to 3.

Figure 1 ROC curve for BMI and eGFR to identify the occurrence of OSA in HCM patients.

Abbreviations: BMI, body mass index; eGFR, estimated glomerular filtration rate; HCM, hypertrophic cardiomyopathy; OSA, obstructive sleep apnea; ROC, receiver operating characteristic.

Further, we analyzed the additive effect of biological interactions, which was set up by Tomas Andersson.²⁵ Table 6 details the measurement results of the three biological interactions. According to AP (0.701, 95% CI: 0.221, 1.181), it was concluded that 70.1% of patients with HCM developed OSA due to the biological interaction of the High BMI and Low eGFR. AP values were more significant after adjusting for confounding factors (0.754, 95% CI: 0.354, 1.155).

Discussion

A main finding in this study was that there were significant multiplicative and additive interactions of BMI and eGFR on the occurrence of OSA in patients with HCM, and the combination of the two factors had a better predictive effect on the occurrence of OSA in HCM patients. This finding was supported by the following results: 1) BMI and eGFR were

Table 4 ROC Analysis for BMI and/or eGFR to Predict OSA in HCM Patients

Variable	Sensitivity	Specificity	Youden's Index	AUC	P value
BMI	0.865	0.471	0.336	0.683	0.008
eGFR	0.559	0.757	0.316	0.700	0.004
BMI and eGFR	0.595	0.912	0.507	0.785	0.000038

Abbreviations: AUC, area under curve; BMI, body mass index; eGFR, estimated glomerular filtration rate; HCM, hypertrophic cardiomyopathy; OSA, obstructive sleep apnea; ROC, receiver operating characteristic.

respectively and independently correlated with the occurrence of OSA in HCM patients (Table 3); 2) BMI and eGFR had significant multiplicative (Table 5) and additive interactions (Table 6) in patients with HCM and OSA; 3) the combination of BMI and eGFR had a better predictive effect on the occurrence of OSA in HCM patients (Figure 1 and Table 4).

HCM is the most common inherited cardiomyopathy and OSA is a significant reversible cause of many cardiovascular diseases including hypertension,⁵ myocardial infarction,⁶ atrial fibrillation (AF),⁷ sudden cardiac death (SCD)⁸ and renal disease.⁹ OSA has been seen to occur concurrently in several cardiovascular diseases including heart failure, and indeed in HCM. In fact, a high prevalence of OSA with a range from 32% to 80% has been previously reported in HCM patients,^{10–15} and OSA is known to increase the risk that contribute to morbidity and mortality in HCM including arrhythmias, myocardial hypertrophy, and SCD.¹⁶ A significant reduction in major adverse cardiovascular events with effective treatment of OSA can be seen in both normal populations and in populations with established cardiovascular diseases.²⁷ In patients with both HCM and OSA, heart functional improvement, left atrial volume reduction, and left ventricular outflow tract obstruction amelioration were shown after continuous positive airway pressure (CPAP) treatment, a most used therapy for OSA.²⁸ It has also been reported that CPAP treatment could terminate recurrent episodes of ventricular tachycardia.²⁹ Therefore, the two conditions occurring together pose a particular challenge in that the identification and appropriate management of OSA in HCM patients.

Though researchers tried to find a predictor to identify the risk of OSA in HCM patients, they discovered that patients with HCM and OSA had no typical clinical symptoms, such as fatigue and excessive daytime sleepiness.¹⁷ Male, age, BMI, hypertension and left ventricular outflow tract obstruction were previously reported correlated with OSA in HCM patients.¹⁸ Although study had shown that the co-presence of these factors might suggest the presence of OSA in patients with HCM,¹⁸ this association had not been constant in other study,¹⁷ including the present study. Obese has been recognized as a risk factor for OSA,^{30,31} however, it was indicated that patients with HCM and OSA were not as obese as the typical OSA patients,³² which was consistent with our previous study showing that OSA patients alone had higher BMI than patients with both HCM and OSA.¹⁹

Interestingly, we previously found that HCM patients with OSA had a higher risk of eGFR decline compared with HCM patients without OSA, indicating eGFR decline could be a characteristic identifying HCM patients with OSA.¹⁹ In the present study, we matched HTN patients who received PSG with HCM patients and found that there was no difference of eGFR between HTN patients with and without OSA. We further found that combination of higher BMI and lower eGFR had a better identification ability of OSA in HCM patients, which seems to be correlated with a multiplicative and additive interaction of high BMI and low eGFR in HCM patients with OSA. These findings might afford the opportunity to increase the alertness of OSA in HCM patients.

In HCM patients, high BMI was shown to be associated with increased left ventricular outflow tract obstruction, which increased the incidence of heart failure and atrial fibrillation.³³ High BMI changes the structure and function of the upper respiratory tract, reduces the power in the central respiratory system and causes hypoxemia.³⁴ These underlying pathogeneses may contribute to the OSA in obesity populations. The mechanism underlying the correlation between eGFR and OSA in HCM patients is not very clear. However, in previous study, nocturnal rostral fluid shift was found to be independently related to the severity of OSA in patients with end-stage renal disease.³⁵ This may be due to the fluid accumulated in the lower limbs during the day would enter the neck slowly during sleep, causing the neck dilated large veins and/or edema of the pharyngeal soft tissue and being prone to upper airway obstruction.³⁵ Such a phenomenon of nocturnal rostral fluid shift could lead to increased neck circumference and upper airway resistance even in non-obese healthy subjects.³⁶

The present study has certain limitations. Firstly, as a major limitation, we were unable to construct a clinical prediction model based on the available data to effectively address the prediction of OSA onset in HCM patients. The development of a clinical prediction model based on the TRIPOD statement should become an important research direction in the future. Secondly, our study is a cross-sectional design, and we could not identify the cause-and-effect association between BMI, eGFR and OSA in the patients with HCM. Thirdly, considering the mildly altered GFR and almost normal BMI in the HCM population of this study, this may somewhat attenuate the performance of both factors in predicting OSA in clinical HCM cases. Fourthly, we did not investigate the effect of weight loss and kidney protection treatment on severity of OSA in HCM patients. Fifthly, the study investigated a relatively small number of patients in a single center. Finally, the mechanism underlying the effect of BMI and eGFR on OSA in HCM patients remains unclear.

Nevertheless, based on our previous finding, the current study further provided the first evidence that a multiplicative and additive interaction of BMI and eGFR in HCM patients could increase the identification ability of OSA in this population. Therefore, warning of high BMI and low eGFR may increase the opportunity for identification and appropriate management of OSA in HCM patients.
