

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

We read with interest the systematic review and meta-analysis by Fiolet et al. [1].

The findings from the systematic review and meta-analysis where hydroxychloroquine, when combined with azithromycin, increased the risk of death, has attracted most of our attention. The findings between observational studies and randomized controlled trial were in contrast; while pooled analysis of observational studies reported an increased risk of mortality, the only randomized controlled trial included in the review reported no difference in the risk of mortality, with the use of the combination of hydroxychloroquine and azithromycin compared with non-use of the combination drugs.

The use of azithromycin could lead to prolongation of the QTc interval, a fact which has also been recognized by the authors. However, the potential for azithromycin to prolong QTc interval may not be the main mechanism leading to increased death seen in patients receiving azithromycin. This is due to the fact that not every form of QT prolongation leads to cardiac arrhythmia or, more specifically, torsades de pointes. Although small prolongation of the QTc interval may be detected in patients receiving azithromycin, such prolongation does not increase the risk of arrhythmia since azithromycin prolongs the action potential, instead of prolonging repolarization which causes torsades de pointes [2].

Whether the use of azithromycin leads to increased risk of death has been an area of dispute even before the coronavirus disease 2019 (COVID-19) pandemic. Similar to the findings reported in the analyses by Fiolet et al. [1], there has been discordance in the findings between real-world observational studies and randomized controlled trials in the settings of clinical trials. The largest observational study thus far with analysis of more than 1 million azithromycin exposures reported that exposure to azithromycin significantly increased the hazard of all-cause mortality (hazard ratio 2.00; 95% CI 1.51–2.63) and cardiovascular death (hazard ratio 1.82; 95% CI 1.23–2.67), with no increased hazard of sudden cardiac death (hazard ratio 1.59; 95% CI 0.90–2.81) [3]. On the other hand, a 2014 meta-analysis of 12 randomized controlled trials with 15 588 patients, of which few trials evaluated long-term use of azithromycin (up to 1 year), reported no increased risk for mortality with the use of azithromycin compared to placebo (risk ratio 0.88; 95% CI 0.75–1.02) [4].

The reason behind such discordance is unclear, but it may be due to more intense monitoring of patients for cardiovascular toxicity in the settings of clinical trials, compared to day-to-day clinical practice, among patients who receive azithromycin. Nonetheless, experimental mice models have discovered the potential for azithromycin to induce a novel proarrhythmic syndrome characterized by rapid, polymorphic ventricular tachycardia in the absence of QTc prolongation, due to intracellular loading of sodium ions with subsequent potentiation of sodium current in the cardiac cells and dysregulation of cardiac calcium homeostasis (similar to digoxin therapy) [5]. The finding warrants further exploration, but in the meantime, perhaps azithromycin should be administered with caution in patients with underlying cardiovascular disease, preferable with intense cardiovascular monitoring, resembling those of clinical trials. This includes patients with COVID-19 *per se* since the pathophysiology of COVID-19 involves myocardial injury.
