Abstract *Background:* Rehabilitation of subacute stroke patients represents a major challenge.

Objective: This study was conducted to examine the effects of mirror therapy on balance ability among subacute stroke patients.

Methods: The patients were assigned to a mirror therapy group ($n = 17$) or a sham therapy group ($n = 17$). Participants in the experimental group received mirror therapy and conventional rehabilitation therapy for a total of 60 minutes (mirror therapy: 30 minutes; conventional rehabilitation therapy: 30 minutes) per day, with a 10 minute rest period halfway through the session. Participants in the experimental group received training 5 days/week for 4 weeks. Participants in the control group received sham therapy and conventional rehabilitation therapy for a total of 60 minutes (sham therapy: 30 minutes, conventional rehabilitation therapy: 30 minutes) per day on the same day. Balance Index (BI) scores were obtained using a balance measurement system.

Results: A significant difference in post-training gains for the overall stability index and medial and lateral stability index was observed between the experimental group and the control group ($p < 0.05$).

Conclusion: We conclude that mirror therapy may be beneficial in improving balance ability among subacute stroke patients.

Introduction

Stroke, the number one cause of neurological disability worldwide, is characterised by both cognitive and motor impairments, as well as balance impairment, which may lead to functional dependence and reduced quality of life [1].

In particular, because of abnormal muscle tone, coordination disorder, and associated reactions, hemiplegic patients experience a considerable decrease of motor function in affected limbs [1]. The impaired lower extremity motor function commonly leads to functional limitations and disability [2].

Damage to balance ability after a stroke decreases stability in the standing position, causing difficulty in walking and performing functional activities. Hence, balance ability is the basis for independent movement and functional performance [3].

Treatments to improve function of stroke patients include constraint-induced therapy [4], mental imagery training [5], and robotic-assisted rehabilitation [6]. However, most intervention protocols are labour intensive, making the provision of intensive treatment for all patients difficult.

Mirror therapy, with its low cost and simplicity, may be a suitable alternative [7,8]. Ramachandran and Rogers-Ramachandran [9] introduced the use of visual illusions created by a mirror as a treatment for phantom pain.

A mirror is placed in the patient's midsagittal plane, with the unaffected limb in front of it, so that the affected limb is blocked and the patient can only see the reflection of the intact limb [10]. Movement of the intact limb gives the patient the illusion in which inputs are perceived through the affected limb behind the mirror.

Studies on the effectiveness of mirror therapy in stroke patients, including a 2012 Cochrane analysis [11], identified methodologically appropriate randomised controlled trials [12]. In addition, Altschuler et al [13] implemented mirror therapy with stroke patients and proved the beneficial effects of mirror therapy on the range of motion of upper extremity joints, motion velocity, and accuracy. Sathian et al [8] found that, after 2 weeks of mirror therapy, a chronic stroke patient recovered hand function and grip strength in the paretic limb.

In previous research, mirror therapy focused mainly on the upper limb functions. However, since damage to lower limb function after stroke affects the independent daily functions, more studies are required to explore the issue of mirror therapy and balance ability which is very much related to the lower limb functions.

This study was conducted to examine the effect of mirror therapy on balance ability in subacute patients (onset within 6 months after a stroke).

Methods

Participants

Patients ($n = 60$) with stroke were screened for this study from March 2014 to August 2014. The inclusion criteria were: (1) sufficient cognitive ability to follow instructions

(Mini-Mental State Examination score ≥ 24) [14]; (2) only mild spasticity in all joints of the affected limb (Modified Ashworth Scale score < 3) [15]; and (3) a higher than fair score on the Manual Muscle test [16].

The exclusion criteria were: (1) muscular-skeletal disorder and operation of the lower extremities; (2) limited range of motion of the lower extremity; (3) unilateral neglect, hemianopsia, or apraxia; and (4) psychological or emotional problems.

Thirty four patients with stroke met the criteria (Figure 1). The Research Ethics Committee of Eulji University Hospital approved the study, and all participants provided written informed consent prior to inclusion in the study. After completion of the initial assessment, the participants were randomly assigned to an experimental group ($n = 17$) or a control group ($n = 17$). For randomisation, sealed envelopes were prepared in advance and marked inside with A or B, indicating the experimental group or the control group respectively. The randomisation was done by a third party who was completely unaware of the study content. The participants' characteristics and all outcome measures before and after the treatment were assessed by Physician 1, who was blinded to the treatment allocations. The mirror therapy and sham therapy were performed by Physician 2, who was not involved in the assessment of the participants, in a closed room. Both physicians were instructed not to communicate with the participants about the possible goals or the rationale of either treatment.

Intervention

Participants in the experimental group received mirror therapy and conventional rehabilitation therapy for a total of 60 minutes (mirror therapy: 30 minutes; conventional rehabilitation therapy: 30 minutes) per day, with a 10 minutes rest period halfway through the session. Participants in the experimental group received training 5 days/week for 4 weeks. Conventional rehabilitation therapy consists of neurodevelopmental facilitation techniques. Subjects in the control group received sham therapy and conventional rehabilitation therapy for a total of 60 minutes (sham therapy: 30 minutes, conventional rehabilitation therapy: 30 minutes) per day on the same day.

Mirror therapy was performed using a modified version of that described in the study by Sütbeyaz et al [17]. A mirror was mounted on a stand tilted toward the paretic side of the body to prevent the participant from viewing the paretic limb. For the experimental group, the reflective surface was kept facing the non-paretic leg. The exercises performed in a semiseated position were: (1) hip-knee-ankle flexion; (2) knee extension with ankle dorsiflexion; and (3) knee flexion beyond 90 degrees. The control group performed the same exercise for the same duration as the experimental group, but the reflective side of the mirror was covered with white fabric. Both the experimental and the control group performed only non-paretic lower limb movements during mirror therapy. Participants did not move their paretic limb. Second, for the balance training in front of a mirror, a method proposed by Vaillant et al [18] was modified. The participants performed the following

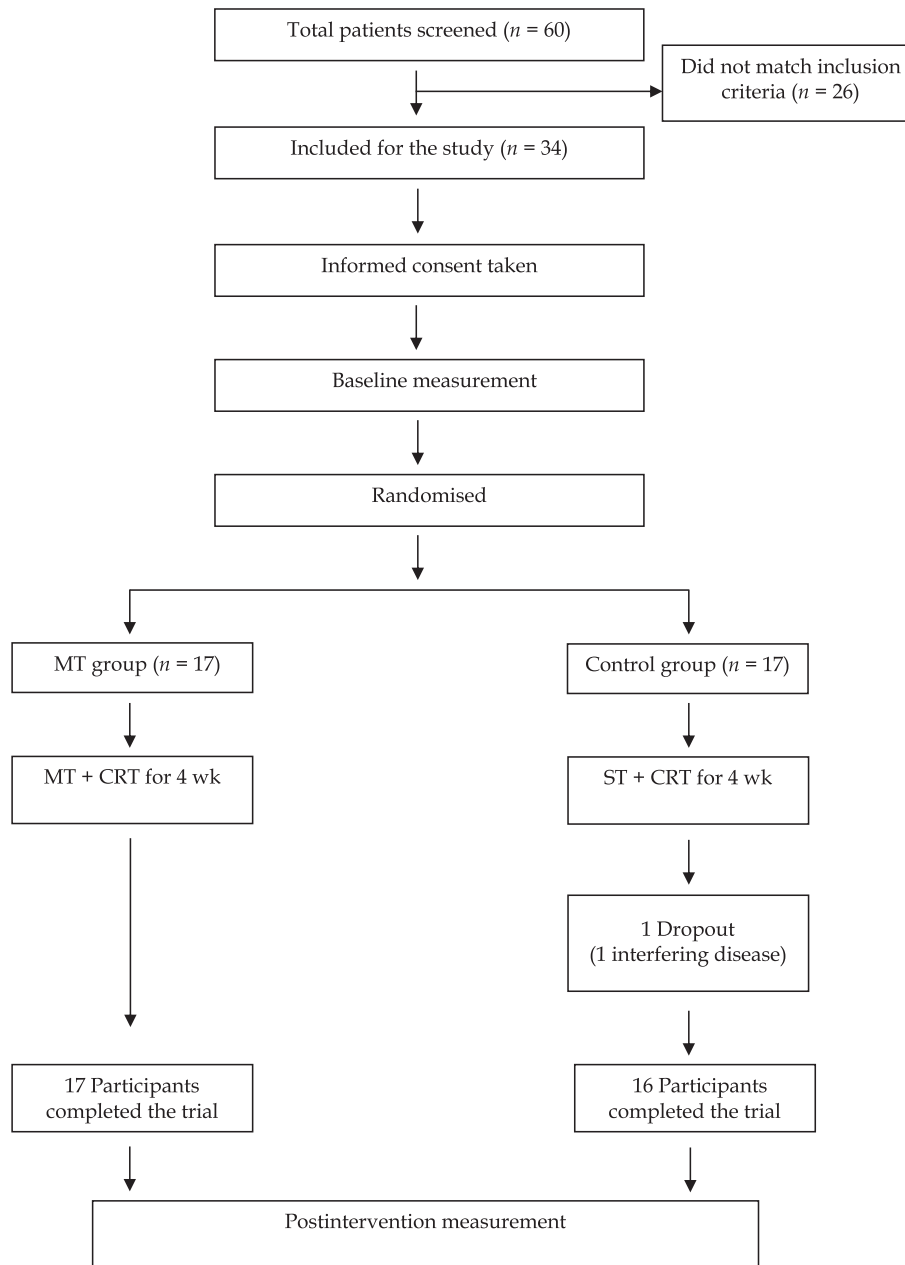

Figure 1. Study flowchart. CRT = conventional rehabilitation therapy; MT = mirror therapy; ST = sham therapy.

actions: placing a chair in front of a full-length mirror and sitting and standing up from the chair, and standing while keeping feet in parallel back and forth. The control group performed the identical training in a space without a mirror.

Outcome measurement

Balance Index

Balance Index (BI) scores were obtained using a balance measurement system (Balance System SD, Biodex, NY, USA), which incorporates a specific monitor and a movable force platform, which provides up to 20° of surface tilt in a 360° range of motion, with a visual feedback system. BI

refers to the participant's ability to maintain the vertical axis of the body within a suitable range of the balance centre of the platform's angle of tilt. A low BI score implies excellent balance ability [19].

In evaluation of balance ability, overall index captures the change of overall movement, anterior/posterior stability index captures the change on the sagittal plane, and medial/lateral stability index captures the change on the frontal plane. That is, the stability index means the movement change of the platform, where a higher value indicates more movement during the test.

The BI has a strong internal consistency, and acceptable intrarater ($r = 0.82$) and interrater ($r = 0.70$) reliability [19].

Table 1 General and medical characteristics of participants ($n = 34$).

	EG ($n = 17$)	CG ($n = 17$)	t/X^2	p
Age (y)	52.4 (7.2)	54.6 (10.2)	-0.548	0.453
Height (cm)	165.6 (6.4)	165.3 (7.1)	0.315	0.882
Weight (kg)	65.6 (9.3)	67.7 (6.9)	-0.432	0.478
Since onset (mo)	4.7 (1.3)	4.5 (1.1)	0.443	0.663
Sex (male/female) (n)	8/9	7/10	-0.336	0.739
Affected side (left/right) (n)	8/9	10/7	0.671	0.507
Type of stroke (ischaemia/ haemorrhage) (n)	12/5	14/3	0.792	0.434
MMSE-K (score)	26.8 (2.2)	26.5 (1.9)	0.427	0.681

CG = control group; EG = experimental group; MMSE-K = Korean version of the Mini-Mental State Examination. Values are presented as mean (SD) unless indicated otherwise.

Statistical analysis

The general characteristics of the participants were tested for homogeneity using the independent t test. Paired t tests were used to verify statistical significance in performances before and after the experiment. An independent t test was performed for comparison between groups. The statistical significance level was set at $\alpha = 0.05$.

Results

As shown in the summary of clinical and demographic features of the sample ($n = 34$) in Table 1, there were no significant differences in the baseline characteristics between the two groups ($p > 0.05$). One participant in the control group gave up the training due to extremely poor health. Therefore, 17 participants (experimental) and 16 participants (control) in each group completed this

experiment. A significant difference in post-training gains for the overall stability index and medial and lateral stability index was observed between the experimental group and the control group ($p < 0.05$) (Table 2).

Discussion

This study was conducted to investigate the effect of mirror therapy on the balance in patients with subacute stroke. According to the results, the treatment group showed a significant decrease of degree in overall stability index and in-and-out stability index after treatment compared to the control group, implying that mirror therapy is effective in improving balance ability.

Several underlying mechanisms have been suggested for the effect of mirror therapy on motor recovery after stroke. Stevens and Stoykov [20] suggested that mirror therapy is related to motor imagery and that the mirror provides visual feedback of the successful performance of the imagined action with the affected limb. Motor imagery itself, the mental performance of a movement without overt execution of this movement, has proven to be beneficial in the rehabilitation of stroke patients [21].

The effect of mirror therapy on brain activity has been investigated in a number of studies. Galeazzi et al [22] reported improvement of balance ability in stroke patients who performed exercise training in front of a full-length mirror. Lynch [23] argued that instant self-analysis and correction for the patients are possible, as they visually confirm their own physical alignment through mirrors. Sütbeyaz et al [17] randomly assigned 40 stroke patients to a mirror therapy group and a control group. The participants repeatedly performed dorsiflexion of the ankles with the non-affected lower limb placed in front of a mirror. In measurement of their functional ambulation categories, the mirror therapy group achieved a statistically significant higher level of improvement in gait ability than the control group.

Functional magnetic resonance imaging (fMRI) images related to mirror therapy found that the primary motor cortex, which is involved in the movements of the other side extremities, was excited by only observing the moving extremities in mirrors [24–26]. This finding shows that the functional organisation of motor systems is achieved not only by the active movements of the ipsilateral extremities, but also by passive observation of the movements of the contralateral extremities [25,26].

Table 2 Comparison of balance within and between groups ($n = 33$) (unit: degree).

	EG ($n = 17$)			CG ($n = 16$)			t	p
	Pre	Post	CWG	Pre	Post	CWG		
Overall ^a	5.29 (0.79)	4.32 (1.12)	0.97 (0.59–1.34)*	5.31 (0.87)	5.08 (0.88)	0.23 (0.19–0.45)*	-2.155	0.038
A/P	4.42 (0.43)	4.10 (0.51)	0.32 (0.10–0.54)*	4.43 (0.45)	4.27 (0.51)	0.16 (0.01–0.31)*	-0.983	0.333
M/L ^a	4.27 (0.42)	3.33 (0.67)	0.94 (0.67–1.21)*	4.06 (0.44)	3.89 (0.45)	0.17 (0.37–0.30)*	-2.816	0.008

Values are presented as mean (SD) except for changes within groups, which are expressed as mean differences (95% confidence intervals).

Overall = overall stability index; A/P = anterior and posterior stability index; M/L = medial and lateral stability index; CG = control group; CWG = changes within groups; EG = experimental group.

^a Significant difference in gains between two groups, $p < 0.05$.

In another study, Altschuler et al [27] reported that application of mirror therapy to chronic stroke patients caused an increase in range of motion and moving speed of upper limbs, along with minute improvement of task performance ability that uses fingers. Cacchio et al [28], who applied mirror therapy to stroke patients, reported significant improvement of upper limb functions, as indicated by the Motor Activity Log and Wolf motor function test scores. Feltham et al [29] showed that visual feedback treatment using a mirror has positive effects on the bilateral coordination ability and neuromuscular activity among spastic hemiplegic patients.

These findings are generally in line with the results of the current study. As a cognitive intervention method, mirror therapy causes activation of the frontal or parietal lobe in the corresponding motor region, an area known as the mirror neurons, through only observing the behaviour of others [30].

Among the assumptions regarding the functional role of mirror neuron, the first one is expressing actions related to those entered into visual and auditory sense in exercise. This means understanding of the observed exercise goal and projecting it in exercise. The ventral premotor cortex and inferior parietal lobe control these reactions. The second assumption is about is realising the conceived emotional situation into motor reaction. Insula and rostral cingulate control these reactions [30].

Therefore, mirror therapy could play an important role in learning a new skill or understanding the behaviour of others, which can be used to motivate stroke patients [17]. Mirror therapy is performed on the non-paralysed side by moving the limbs of stroke patients; the movement of paralysed limbs through the reflection in the mirror shows a visual illusion of normal movement. This method for treating a brain injury is based on the principle of synaptic plasticity [17].

The current study has some limitations. First, the small sample size may have influenced the results. Second, the absence of follow-up after the end of the mirror therapy does not allow for determination of the durability of the effect of this therapy. Third, individual musculoskeletal and neurologic variations, which is important in patient evaluation, was not considered. This can be a significant factor affecting the research results regarding the improvement of balance ability. Finally, the study does not include diverse evaluation of the walking ability and independent daily routine which are important in quality of life. Therefore, these results can be generalised to subacute stroke patients. Further studies, including a long-term follow-up assessment, are needed to evaluate the long-term benefits of mirror therapy.

Conclusion

Mirror therapy may be beneficial in increasing the balance ability of subacute stroke patients. The data should be interpreted with caution due to the small sample size. A large-scale randomised controlled trial is required in order to confirm our findings and further evaluate the long-term effects of mirror therapy in patients after stroke.
