ABSTRACT

Objectives To investigate the prognostic value of neutrophil-to-albumin ratio (NAR) in critically ill patients with cardiogenic shock (CS).

Design A retrospective cohort study.

Setting A single centre in Boston, USA.

Participants 475 patients with CS were included, among which 272 (57.3%) were men and 328 (69.1%) were white.

Primary and secondary outcome measures The primary outcome was 90-day mortality and the secondary outcomes were 30-day and 365-day mortality.

Results A significant positive correlation between NAR levels and 90-day, 30-day or 365-day mortality was observed. For 90-day mortality, the adjusted HR (95% CI) values given NAR levels 23.54–27.86 and >27.86 were 1.71 (1.14 to 2.55) and 1.93 (1.27 to 2.93) compared with the reference (NAR<23.47). Receiver operator characteristic curve analysis showed that NAR had a certain prognostic value in predicting 90-day mortality of CS, which was more sensitive than the neutrophil percentage or the serum albumin level alone (0.651 vs 0.509, 0.584). For the secondary outcomes, the upward trend remained statistically significant.

Conclusions NAR level was associated with the mortality of CS patients. The prognostic value of NAR was more sensitive than the neutrophil percentage or the serum albumin level alone, but not as good as Sequential Organ Failure Assessment or Simplified Acute Physiology Score.

INTRODUCTION

Cardiogenic shock (CS), a lethal complication of cardiac emergencies, is traditionally thought to begin with depression of myocardial contractility, followed by intractable hypotension, coronary insufficiency and further loss of cardiac output, causing multiple organ failure and eventually death.^{1 2} For decades, the prevalence of CS has risen from 4.1% to 7.7% of all admissions to the intensive care unit (ICU),³ of which approximately 6.4%–40% mortality were reported despite intensive care.^{4 5} Hence, considering the high mortality of CS in ICU,

Strengths and limitations of this study

- This was the first study to explore the prognostic effect of neutrophil-to-albumin ratio (NAR) in patients with cardiogenic shock.
- Multivariate Cox proportional hazards model was applied in the study.
- This was a retrospective observational study in a single centre.
- The sample size of patients selected was small.
- NAR was measured only when patients first admitted to the intensive care unit.

finding effective and convenient prognostic biomarker may be beneficial to assist physicians to make medical decisions and identify patients at high risk.^{6–8}

Inflammation plays an important role in the pathogenesis of CS.⁹ Among the inflammatory mediators, the neutrophil, well known as a marker of inflammation,¹⁰ has been widely studied regarding the development of various diseases, including CS. Serum albumin level was shown to be associated with cardiovascular mortality.^{11 12} Also, neutrophil or albumin has already been used in several clinical scoring systems. However, it is unclear whether the combination of neutrophils and albumin has a higher prognostic value. Neutrophil-to-albumin ratio (NAR), an integrated biomarker of neutrophils and albumin, is a cost-efficient and readily available biomarker which can be easily obtained from routine blood test. Recently, NAR has been used to evaluate the prognosis of cancer,^{13 14} but to the best of our knowledge, no study has explored the prognostic significance of NAR in patients with CS. Therefore, we performed a retrospective cohort study to identify the associations between NAR and mortality in patients with CS.

MATERIAL AND METHODS

Data source

All data in our study were extracted from the Medical Information Mart for Intensive Care Database III V.1.4 (MIMIC-III V.1.4), a large, open, free and single-centred database including information from more than 50 000 adult patients admitted to various critical care units at Beth Israel Deaconess Medical Center (Boston, MA, USA) from 2001 to 2012.¹⁵ The setting and use of this database were approved by the institutional review boards of the Massachusetts Institute of Technology (Boston, MA) and Beth Israel Deaconess Medical Centre (Cambridge, MA). All personal information included in the database have been de-identified to safeguard privacy.

Population selection criteria

More than 50 000 ICU admissions to the MIMIC-III database were recorded, and only patients diagnosed with CS were extracted. Among these patients, we selected those who attained more than 16 years of age at first admission while remained in the hospital for more than 48 hours. Exclusion criteria were as follows: (1) patients diagnosed with haematologic neoplasms, including leukaemia, lymphoma, myelodysplastic syndrome, multiple myeloma and others; (2) more than 10% individual data were missing; (3) individual data values exceeded the mean \pm 3 times the SD.

CS was determined according to the Ninth Revision of International Classification of Diseases, coded as R57.001. CS was defined that the systolic blood pressure (SBP) dropped below 90 mm Hg for more than 30 min or a need for catecholamine to maintain SBP above 90 mm Hg and also signs of end-organ hypoperfusion occurred (urine volume <30 mL/h, lactic acid >2.0 mmol/L, cold extremities or altered mental status).

Date extraction

Data were extracted through Structured Query Language (SQL)¹⁶ with MySQL tools from MIMIC-III. We extracted the baseline data within 24 hours at patients' first admission, containing demographic parameters, basic vital signs, laboratory indicators and scoring systems.

Demographic parameters contained age, gender and ethnicity, while basic vital signs included SBP, diastolic blood pressure (DBP), mean blood pressure (MBP), heart rate, respiratory rate, temperature and percutaneous oxygen saturation (SPO₂). The following laboratory indicators were extracted: neutrophils, albumin, white blood counts (WBC), haematocrit, haemoglobin, platelet count, serum bicarbonate, serum sodium, serum potassium, serum chloride, serum glucose, serum bilirubin, blood urea nitrogen (BUN), serum creatinine (SCr), partial thromboplastin time (PTT), prothrombin time (PT) and international normalised ratio (INR). We additionally extracted relevant comorbidities, like congestive heart failure (CHF), coronary heart disease (CHD), atrial fibrillation (AF), stroke, chronic obstructive pulmonary

disease (COPD), pneumonia, acute respiratory distress syndrome and other diseases.

Severity-of-illness scores, including the Sequential Organ Failure Assessment (SOFA)¹⁷ score and the Simplified Acute Physiology Score II (SAPS II)¹⁸ were also calculated for every individual. These scores were assessed and calculated on the basis of published recommendations and accepted formulas.

The primary outcome was 90-day mortality and the secondary outcomes were 30-day mortality and 1-year mortality. Follow-up began when the patients first admitted to the ICU. The date of mortality was got from Social Security Death Index records.

Assessment of NAR

NAR was defined as the ratio of neutrophil percentage to serum albumin level. The indicators both came from the first measured data within 24 hours of ICU admission. Neutrophil percentage was analysed by the automatic flow cytometer, while albumin level was generated by biochemical analyser.

Statistical analysis

Categorical data were shown as frequency (percent), while continuous ones as mean (SD) or median (IQR). We did comparisons between groups by the χ^2 test¹⁹ or Fisher's exact test²⁰ for categorical variables and the variance analysis or the Kruskal-Wallis test²¹ for continuous ones.

Cox proportional hazards models²² were used to examine the associations between NAR and outcomes. The outcomes were respectively analysed according to the tertiles of the NAR level. The first tertile group was regarded as the reference group. The results were presented as HRs with 95% CIs. Multivariate analyses were performed using two adjusted models. The confounders selected in our models were based on their associations with outcome or a change in the effect estimate exceeding 10%.²³ In model I, we adjusted covariates for age, gender and ethnicity. In model II, covariates were adjusted further for SBP, DBP, heart rate, respiratory rate, SPO₂, anion gap, serum bicarbonate, serum potassium, SCr, BUN, haematocrit, platelet count, WBC count, PTT, PT, INR, stroke, pneumonia, COPD, chronic liver disease, chronic renal disease, malignancy, vasoactive agent, renal replacement therapy (RRT), SOFA score and SAPSII score. The trend tests were performed to examine the differences between groups.

In addition, we performed stratification analysis to confirm whether the effect of NAR differs in each of the subgroups that were classified by vital signs (eg, SBP, DBP, heart rate, respiratory rate, temperature, SPO₂), laboratory parameters (eg, anion gap, serum bicarbonate, serum sodium, serum potassium, serum chloride, serum bilirubin, serum glucose, SCr, BUN, haematocrit, haemoglobin, WBC count, platelet count, PTT, PT, INR), comorbidities (CHD, CHF, AF, stroke, pneumonia, respiratory failure, chronic liver disease, chronic renal disease, RRT,

malignancy), vasoactive drug use and scoring systems (SOFA and SAPSII scores).

To further assess the predictive value of NAR, we did receiver operator characteristic (ROC) curve analysis for the 90-day mortality according to the neutrophil percentage, the serum albumin level, NAR, SOFA score and SPASII score.

A two-tailed $p < 0.05$ was deemed statistically significant. We applied EmpowerStats V.2.17.8 (<http://www.empowerstats.com/cn/>) and R software V.3.42 for all statistical analysis.

RESULTS

Patient characteristics

After excluding the patients who did not meet the inclusion criteria, a total of 475 patients were included. Among the patients included, 272 (57.3%) were men and 328 (69.1%) were white.

We divided the patients into three groups according to the tertiles of NAR. Baseline characteristics classified by NAR tertiles were presented in table 1. Patients in the higher NAR group tended to be white and had higher serum chloride, BUN, WBC count, PTT, PT, INR and lower serum bicarbonate, haematocrit, haemoglobin. Patients with higher NAR also had a higher SOFA and SAPSII scores than those with lower NAR (<23.47). These patients, however, had no apparent differences in age, gender, vital signs, vasoactive drug use or comorbidities.

NAR levels and mortality

A total of 180, 218 and 264 deaths were recorded in the 30-day, 90-day and 365-day follow-up periods, respectively. Results of the relationship between NAR and mortality in CS patients were shown in table 2 and figure 1.

For the primary outcome of 90-day mortality, we found that higher NAR was related to increased risk of mortality. The HR (95% CI) values of the mid-tertile (NAR=23.54–27.86) and the upper tertile (NAR>27.86) were 1.56 (1.10 to 2.22) and 1.95 (1.39 to 2.73), respectively, when compared with the reference (NAR<23.47). After adjusted for age, gender and ethnicity in model I, an increasing trend was also observed and the adjusted HR (95% CI) values for 90-day mortality given NAR of 23.54–27.86 and >27.86 were 1.50 (1.06 to 2.13) and 1.99 (1.42 to 2.80). After further adjusted for potential confounders in model II, the upward trend remained statistically significant (mid-tertile: 1.71 (1.14 to 2.55); upper tertile: 1.93 (1.27 to 2.93)).

The similar trends were also observed for the secondary outcomes of 30-day and 365-day mortality.

Subgroup analysis

Subgroup analysis was conducted to determine the consistency of association between NAR and 90-day mortality in patients with CS. Partial results were shown in table 3 and the full results were in the online supplemental table. Most subgroup factors showed low significance with 90-day mortality, except for the serum sodium

Table 2 Association between NAR and mortality in CS patients

Models I and II were derived from Cox proportional hazards regression models: model I covariates were adjusted for age; gender; ethnicity; model II covariates were adjusted for age; gender; ethnicity; heart rate; SBP; DBP; respiratory rate; SPO₂; anion gap; serum bicarbonate; serum potassium; SCr; BUN; haematocrit; platelet count; WBC count; PTT; PT; INR; stroke; pneumonia; COPD; chronic liver disease; chronic renal disease; RRT; malignancy; vasoactive agent; SOFA; SAPSII.

BUN, blood urea nitrogen; COPD, chronic obstructive pulmonary disease; CS, cardiogenic shock; ; DBP, diastolic blood pressure; INR, international normalised ratio; NAR, neutrophil-to-albumin ratio; PT, prothrombin time; PTT, partial thromboplastin time; RRT, renal replacement therapy; SAPSII, Simplified Acute Physiology Score; SBP, systolic blood pressure; SCr, serum creatinine; SOFA, Sequential Organ Failure Assessment; SPO₂, percutaneous oxygen saturation.

($p=0.0270$), the serum bilirubin ($p=0.0343$), respiratory failure ($p=0.0102$) and RRT ($p=0.0044$). NAR particularly showed significant interactions in patients without RRT. Patients without the therapy of RRT had a significant higher 90-day mortality risk for NAR>27.86 (HR (95% CI): 2.29 (1.58 to 3.32)). In addition, patients without respiratory failure also had higher mortality risks.

Figure 1 HRs (95% CIs) for mortality across tertile groups of NARs. (Tertiles: model I and model II). NAR, neutrophil-to-albumin ratio.

ROC curve analysis

ROC curve analysis (figure 2) was performed to further test the potential prognostic value of NAR in predicting the survival of CS patients. Compared with the neutrophil percentage or the serum albumin level alone, NAR was more sensitive in predicting 90-day mortality of CS (AUC: 0.651 vs 0.509, 0.584). The C statistic for NAR, however, was lower than that of SOFA or SAPSII scores (0.651 vs 0.686, 0.737). However, when ROC curve analysis was performed combining NAR and SOFA score or SAPS II, NAR contributed very little to these already known and well-consolidated prognostic indices (figures 3 and 4).

DISCUSSION

In our study, we found a significant positive association between NAR levels and mortality in patients with CS. In particular, a high level of NAR was associated with growing risk of mortality. In addition, NAR was more sensitive in predicting mortality of CS than the neutrophil percentage

NAR, neutrophil-albumin ratio.;

or the serum albumin level alone. The predictive value of NAR, however, was not as good as SOFA or SAPSII score.

CS is a lethal complication of cardiovascular diseases with an extremely high mortality. Inflammation has been shown to play a vital role in the pathogenesis of CS. Studies in recent decades have suggested the prognostic value of inflammatory mediators in CS, including blood cells,²⁴ cytokines,^{25 26} complement²⁷ and enzymes.^{28 29} Furthermore, the use of albumin, the main serum protein, to predict the mortality of cardiovascular disease as well as all-cause mortality has already been described.^{11 30 31} Recent studies have combined these inflammatory mediators to predict the outcome of diseases. The NAR, a combination of the neutrophil percentage and the serum albumin level, is a novel and readily available biomarker. Prior to our work, the prognostic value of NAR has recently been shown. Samuel *et al*¹⁴ demonstrated that NAR was a significant prognostic marker in patients with palliative

pancreatic cancer. Tawfik *et al*¹³ investigated the association between NAR and pathological complete response in rectal cancer patients after neoadjuvant chemoradiation. Based on these evidences, an inference may be put forward that NAR could predict the mortality in patients with CS.

It remains unclear why NAR, the combined biomarker, could have such a significant prognostic value in patients with CS. On the one hand, neutrophil, which is a vital type of leucocytes, has been well studied regarding the development of various diseases, including CS. Sionis *et al*³² recently found that distinct microparticles released by neutrophils (CD15+) significantly increased in patients with CS. This result suggested high activation of neutrophils in CS and further indicated the significance of inflammation in that condition. Given the severe systemic inflammatory response in CS, it has been demonstrated that patients with higher leucocyte count

AUC, area under the curve; CS, cardiogenic shock; NAR, neutrophil-to-albumin; SOFA, Sequential Organ Failure Assessment; SAPSII, Simplified Acute Physiology Score; ROC, receiver operator characteristic curve.

had a higher mortality in CS.³³ However, whether the increase of inflammatory mediators in CS results from the heart itself, from intestinal bacterial translocation, or from ischemia-reperfusion injury remains unknown.⁹ On the other hand, serum albumin, synthesised in the liver, is the major plasma protein in human blood. Albumin has already been used to predict mortality especially in

critically ill patients in ICUs.^{34 35} It has already become a part of major risk scores, such as the Acute Physiology and Chronic Health Evaluation III Prognostic system. Low albumin levels were demonstrated to be related to some inflammatory mediators;^{36 37} therefore, the association between serum albumin and mortality may result from subclinical inflammation, as Mutsert *et al*³⁸ found in their study. However, whether the prognostic value of albumin only reflects inflammation or whether there is an independent role of albumin itself remains to be clear. As albumin plays an important role in maintaining the plasma colloid osmotic pressure, low albumin levels may disorganise the fluid distribution in the internal environment so as to destroy the balance of the haemodynamics, resulting in poor outcomes.³⁹ Another interpretation may involve the state of nutrition. Studies have shown that low albumin may be related to malnutrition, emaciation or cachexia.⁴⁰ However, other studies have indicated that albumin is a lousy nutrition marker. The relationship between albumin and nutritional status remains controversial. Furthermore, as the most abundant carrier protein in plasma, albumin can change the existing form of some toxins by binding to them, leading to changes in their biological effects. The recent study of Watanabe *et al*⁴¹ indicated that, when combined with lower albumin levels, levels of indoxyl sulfate, a protein-bound uremic toxin, might be a prognostic marker for cardiovascular diseases, because lower albumin levels might increase free indoxyl sulfate levels, possibly activating a signal transduction pathway and subsequently exerting toxic effects. Further studies are needed to confirm these hypotheses.

CS in critically ill patients has an extremely high mortality. This poor outcome may be affected by a number of factors, including basic vital signs (ie, DBP,⁴² MBP),⁴³

some laboratory parameters (ie, serum bicarbonate levels,⁴⁴ cardiac power index,⁴³ vasopressor support),⁴⁵ severity-of-illness scores (ie, SAPSII),⁴³ as well as other comorbidities. In subgroup analysis, patients were stratified according to potential confounders and statistically significant interactions were observed for some factors, such as respiratory failure and RRT. Patients without a history of respiratory failure or without the therapy of RRT might have a higher risk of 90-day mortality. In patients with the therapy of RRT, prognosis might be meliorated through metabolites clearance. While in patients with a history of respiratory failure, the improved survival might contribute to the systemic antimicrobial therapy and advanced assisted ventilation strategies. The real mechanism, however, remained unclear.

Our study was the first study to explore the prognostic effect of NAR in patients with CS. The period of follow-up in our study was quite long. The limitations of this study, however, cannot be ignored. First and foremost, it was a retrospective observational study in a single centre. The biases inherent in this type of study and selection bias in this design should be highlighted. Therefore, we should further perform studies based on multiple centres. Second, owing to the relatively low incidence of CS, the sample size of patients selected in our study was small, suggesting that larger prospective studies are needed. Third, NAR was measured only when patients first admitted to the ICU, possibly causing biases to a certain extent. Therefore, the dynamic evaluation of NAR during the ICU stay can make a difference. Furthermore, merely measuring NAR does not adequately reflect genuine levels of inflammation. Therefore, simultaneous measurement of other inflammatory factors would make a better demonstration of our conclusions. Last but not the least, to set up NAR as a prognostic biomarker, its clinical significance must further be verified.

CONCLUSIONS

NAR level was associated with the mortality of CS patients. NAR was an potential prognostic biomarker of mortality in CS patients. Its predictive value was more sensitive than the neutrophil percentage or the serum albumin level alone, but not as good as SOFA or SAPSII score. However, further prospective studies with larger sample size are needed to confirm our findings.
