## Abstract

**Background:** The *Passiflora* genus comprises hundreds of wild and cultivated species of passion fruit used for food, industrial, ornamental and medicinal purposes. Efforts to develop genomic tools for genetic analysis of *P. edulis*, the most important commercial *Passiflora* species, are still incipient. In spite of many recognized applications of microsatellite markers in genetics and breeding, their availability for passion fruit research remains restricted. Microsatellite markers in *P. edulis* are usually limited in number, show reduced polymorphism, and are mostly based on compound or imperfect repeats. Furthermore, they are confined to only a few *Passiflora* species. We describe the use of NGS technology to partially assemble the *P. edulis* genome in order to develop hundreds of new microsatellite markers.

**Results:** A total of 14.11 Gbp of Illumina paired-end sequence reads were analyzed to detect simple sequence repeat sites in the sour passion fruit genome. A sample of 1300 contigs containing perfect repeat microsatellite sequences was selected for PCR primer development. Panels of di- and tri-nucleotide repeat markers were then tested in *P. edulis* germplasm accessions for validation. DNA polymorphism was detected in 74% of the markers (PIC = 0.16 to 0.77; number of alleles/locus = 2 to 7). A core panel of highly polymorphic markers (PIC = 0.46 to 0.77) was used to cross-amplify PCR products in 79 species of *Passiflora* (including *P. edulis*), belonging to four subgenera (*Astropheae*, *Decaloba*, *Distephana* and *Passiflora*). Approximately 71% of the marker/species combinations resulted in positive amplicons in all species tested. DNA polymorphism was detected in germplasm accessions of six closely related *Passiflora* species (*P. edulis*, *P. alata*, *P. maliformis*, *P. nitida*, *P. quadrangularis* and *P. setacea*) and the data used for accession discrimination and species assignment.

**Conclusion:** A database of *P. edulis* DNA sequences obtained by NGS technology was examined to identify microsatellite repeats in the sour passion fruit genome. Markers were submitted to evaluation using accessions of cultivated and wild *Passiflora* species. The new microsatellite markers detected high levels of DNA polymorphism in sour passion fruit and can potentially be used in genetic analysis of *P. edulis* and other *Passiflora* species.

**Keywords:** De novo genome assembly, Microsatellite, Cross-species transferability

## Background

*Passiflora* is a highly diverse genus with approximately 520 species distributed in tropical regions of America, Asia and Africa [1]. Despite taxonomical uncertainties, approximately 96% of the *Passiflora* species are found in South and Central America [2]. Major centers of diversity include regions of Brazil and Colombia [3, 4], both countries with hundreds of species catalogued. However, just a few *Passiflora* species are used in agriculture, mostly for production of fruits, which are consumed *in natura* or as juice. Passion fruit species are also used as ornamentals, in the food industry and for medicinal purposes.

Sour passion fruit (*P. edulis*) is by far the most important commercial *Passiflora* species worldwide. It is an allogamous species, displaying a well documented variability of shapes and colors of fruits, flowers and plants. Genetic diversity in *P. edulis* has been assessed by morphological descriptors [5–7] and agronomic traits [8–10]. Detection of DNA polymorphism in *P. edulis* has been pursued with different types of molecular markers, such as Inter Simple Sequence Repeat (ISRR) [11], Random Amplified Polymorphic DNA (RAPD) [12–14], Amplified Fragment Length Polymorphism (AFLP) [15, 16] and microsatellites [17–19]. High levels of genetic variability have been recorded in morphological and agronomic evaluations of sour passion fruit, as well as in most marker systems. However, the use of microsatellite markers in genetic analysis of *P. edulis* underscores low DNA polymorphism [16–18] in an otherwise highly diverse species.

Advantages of microsatellite markers over other technologies include high reproducibility, co-dominance, high polymorphic information content (PIC) and multi-allelism [20–22]. Less than 200 microsatellite markers have been developed for *P. edulis* [17, 19, 23] and only a small fraction of these markers have been validated and used in genetic studies [16, 23–25]. The few polymorphic *P. edulis* microsatellite markers are based on compound or imperfect motifs, which are hard to interpret on routine genotyping assays due to allele binning difficulties [26, 27]. This could be a constraint to some applications, especially for population genetic studies [28, 29]. Perfect microsatellite markers (i.e. repeat of the same nucleotide motif without interruption or variation) would be more suitable, but they are only a small fraction (~10%) of the total number of *P. edulis* markers [17, 19, 23]. Also, the use of microsatellite markers in *Passiflora* has been limited to a few species, such as *P. edulis* [17, 19, 23], *P. alata* [30, 31], *P. cincinnata* [18, 19], *P. setacea* [19], and *P. contracta* [32]. This is only a tiny fraction (~1%) of the known *Passiflora* species. Similar constraints to microsatellite marker availability and use are also observed in other *Passiflora* species. Therefore, although

there is a wide number of applications of microsatellite markers in genetics and breeding, their development and availability for passion fruit research is still restricted.

Microsatellite detection and isolation has been most often based on enrichment of genomic libraries by selective hybridization [33] or by primer extension [34]. Another approach is to identify microsatellite repeats in DNA databases such as EST sequences [35]. The development of microsatellite markers in *Passiflora* has been based on the construction of genomic libraries enriched for simple sequence repeats [17–19, 23, 30–32]. This is an effective but time and labor consuming technique that can lead to microsatellite discovery and marker development. However, new approaches such as next-generation sequencing (NGS) can provide a large number of high quality genome sequences that can be obtained faster and at reduced costs, facilitating the detection of thousands of microsatellite sites in the genome of a target species [36–39].

In the present study we used NGS to sequence the *P. edulis* genome. We then screened contig sequences obtained by partial de novo assembly to detect perfect microsatellite sites. This data was used to develop and validate microsatellite markers using *P. edulis* accessions of the germplasm bank. Markers were then evaluated for quality and polymorphism in *P. edulis* and five closely related *Passiflora* species and, also, for cross-species transferability to 78 *Passiflora* species belonging to four subgenera (*Astropheae*, *Decaloba*, *Distephana* and *Passiflora*), recently collected in Brazil.

## Methods

**DNA extraction and genome sequencing** – Fresh young leaves of the accession *Passiflora edulis* CPGA1, a sour yellow rind commercial cultivar of passion fruit, were used for DNA extraction with the standard CTAB protocol [40]. The construction of the genomic DNA fragment library and massive parallel paired-end sequencing by synthesis using an Illumina GAII sequencer followed the Illumina protocol.

**De novo genome assembly** – The presence of non-nuclear and/or exogenous DNA sequences on the passion fruit DNA database was verified by BLASTing it against a database of chloroplast, mitochondrial and potential contaminant DNA (fungi, bacteria and virus). Extraneous sequences were removed from the analysis. The short-read correction tool of SOAPdenovo (Release 1.05), used to correct Illumina GA reads for large plant and animal genomes [41], was applied to FASTQ formatted files containing DNA sequencing reads. The CLC trimmer function (default limit = 0.05) (CLC Genomics Workbench 4.1 software, CLC Bio, Aarhus, Denmark) was then used to eliminate Illumina sequencing adapters

and low quality reads. ErrorCorrection routines and KmerFreq were run with default parameters (seed length = 17, quality cutoff = 5). Final FASTQ files were submitted to de novo assembly routines using a bubble size of 50 bp on the CLC Genomics Workbench (Assembly Length Fraction = 0.5; Similarity = 0.8), followed by a scaffolding procedure by MipScaffolder [42]. Mismatch, deletion and insertion cost parameters were set to 2, 3 and 3, respectively. The k-mer size on CLC Bio assembler was set to 25 bp and the coverage cutoff to 10X. During assembly, the default word length parameter was adjusted to 25, using k-mer (de Bruijn graph k-mer) overlap information in order to assure unambiguous paths of resulting contigs. The fraction of short insert size contigs >160 bp was considered in the analysis. Overlaps between sequences were depicted by de Bruijn graph structures [43].

**Identification of microsatellite sites and marker development** – The partial de novo sequence assembly results were submitted to simple sequence repeat loci identification using PHOBOS [44]. The location and number of di-, tri-, and tetra-nucleotide SSRs in the draft de novo genome assembly were listed and quantified. Sequence repeats located in putative coding regions were identified with the gene model version TAIR 9 using *P. edulis* contigs blasted against *Arabidopsis thaliana* transcripts (AtGDB171). An ab initio prediction of coding regions was also performed using *geneid* [45] [<http://genome.crg.es/software/geneid/>]. Both analyses were considered for the selection of microsatellites located in structural and coding regions. Only microsatellite sites located in genomic regions with minimum 15X coverage were considered for marker development. A database of simple sequence repeats with four or more di-nucleotide repeats and three or more tri- and tetra-nucleotide repeats was created. Microsatellite loci showing a simple motif exactly repeated in tandem (“perfect microsatellite”) were listed and those with compound (more than one motif) or imperfect repeats were set aside. Perfect microsatellites with minimum 3× motif repeat and located on contigs with minimum 2.5 Kb length and 20X average coverage, as an attempt to maximize loci independence and marker quality, composed the group of selected markers. Finally, PCR primer pairs for 816 perfect microsatellite loci were developed with Primer3Plus [46].

**Plant materials and microsatellite marker descriptive statistics** – Ten accessions of sour passion fruit (*P. edulis* Sims), maintained by the Passion Fruit Germplasm Bank, Embrapa Cerrados, Planaltina, DF, were used to evaluate if the new set of markers is suitable for genetic analysis of passion fruit. Passport data of the passion fruit accessions used in the present study is described on Table 1 (rows 1 to 10). These accessions represent a diverse group of cultivars and local varieties collected in

different regions of Brazil. The only exception is accession “Gulupa” from Colombia. This accession, however, is believed to have been originally collected in Brazil and later introduced in Colombia [47, 48] and was, therefore, also used in the analysis. These ten *P. edulis* accessions were genotyped with a random sample of 60 di- and tri-nucleotide microsatellites. Marker polymorphism, number of alleles, heterozygosity, PIC values and other statistics were estimated by CERVUS [49].

### Cross-species transferability of *P. edulis* microsatellite markers

In order to test the potential cross-species transferability of novel *P. edulis* microsatellite markers to other *Passiflora* species, we genotyped 90 accessions belonging to 78 *Passiflora* species native to Brazil (Table 1, rows 12 to 101), maintained by the Passion Fruit Germplasm Bank, Embrapa Cerrados, Planaltina, DF. These passion fruit species belong to four subgenera (*Astrophea*, *Decaloba*, *Distephana* and *Passiflora*). These accessions were genotyped with 18 polymorphic markers out of a sample of 60 markers initially selected for testing. Successful PCR amplifications were recorded as presence or absence of amplicons if the allele sizes were detected in the approximate expected range.

For most *Passiflora* species, only one accession was represented in the Germplasm Bank. However, for those species with two to five accessions available, cross-amplification and marker polymorphism could be computed (Table 1). Allele frequencies observed in 27 accessions of six species (*P. edulis*, *P. alata*, *P. maliformis*, *P. nitida*, *P. quadrangularis* and *P. setacea*) plus accession 11 (Table 1, BRS Maracujá Jaboticaba) were used to estimate pairwise genetic distances using the Band coefficient [50]. BRS Maracujá Jaboticaba is an autogamous variety of sour passion fruit of unknown phylogeny which produces small fruits of purple rind. Genetic similarities detected by microsatellite markers was explored by Principal Coordinate Analysis (PCoA) using NTSYSpc v.2.10 [51]. An analysis of population structure and ancestry of these 28 accessions based on Bayesian statistics, without prior assignment to species, was also performed using Structure v.2.3.4 [52, 53]. Batch runs with correlated and independent allele frequencies among inferred clusters were tested with population parameters set to admixture model (burn-in 250,000; run-length 500,000). In order to identify the number of clusters in the sample of *Passiflora* accessions, the values of  $\ln P(D)$  were obtained for tests of K ranging from 1 to 10 using 20 independent runs for each K (length of burnin period: 50,000; number of MCMC reps after burnin: 50,000). The most probable value of K for each test was detected by delta K [54]. *Passiflora* accessions were allocated to a cluster if Q

values were greater or equal to 0.70, or otherwise considered as intermediate or admixed. DNA extraction and quantification of all passion fruit accessions followed the procedures described above.

**Microsatellite marker PCR assays** - Multiplex panels for simultaneous evaluation of microsatellite markers were designed using Multiplex Manager [55]. PCR assays were carried in a final volume of 5  $\mu$ L containing 5 ng of genomic DNA, 1X QIAGEN Multiplex PCR Kit Master Mix (QIAGEN), 0.5X Q-Solution (QIAGEN), and 0.2  $\mu$ M of each primer. Reactions were performed on a Veriti™ Thermal Cycler (Applied Biosystems, USA) using the following amplification program: 95 °C for 15 min; 35 cycles at 94 °C for 30 s, 55, 57 or 60 °C for 90 s, and 72 °C for 60 s; followed by a final extension step at 60 °C for 60 min. We added 9  $\mu$ L of Hi-Di™ Formamide (Applied Biosystems, USA) and a ROX-labeled internal size standard to 1  $\mu$ L of the PCR product and denatured at 94 °C for 5 min. Denatured products were injected on an ABI3730 (Applied Biosystems, USA) automated sequencer. Allele size calling and genotyping were carried out with GeneMapper® v4.1 (Applied Biosystems, USA). Automated allelic binning was performed with Tandem [56]. Fisher's exact test was used to test the association between the level of marker polymorphism and the repeat size (di- or tri-nucleotide) using the MedCalc Statistical Software v.12.7.7 [http://www.medcalc.org; 2013].

## Results

Partial sequencing and de novo assembly of the *Passiflora* genome for microsatellite site detection.

Sequence assembly was based on 225,293,527 short read DNA sequences (average length = 62.65 bp), representing 14.1 Gbp (Table 2), which corresponds to  $\sim$ 4.5 $\times$

coverage of the passion fruit genome, assuming a genome size of 3126 Mbp [57]. A total of 234,239 contig segments showing variation in size from 166 to 45,662 bp, average size of 707 bp and covering 165,702,691 bp, were examined for the presence of microsatellite sites. The genome sequences of the *P. edulis* genome have been deposited in GenBank under the BioProject ID SUB2376276.

A batch of 1,972,843 microsatellite sites matched the criteria set for simple sequence repeat discovery in the assembled contig segments (Table 2). Perfect microsatellite included 360,162 di-nucleotide repeats with the number of repeats ranging from 3 to 20 (13,391 > 5 repeats). Perfect tri-nucleotide repeats included 60,669 sites ranging from 3 to 14 repeats (1436 > 5 repeats). Perfect tetra-nucleotide repeats included 7463 sites ranging from 3 to 13 repeats (186 > 5 repeats).

Sequence analysis of *P. edulis* contigs allowed 37,761 gene annotations and identified 5947 sequence repeats located in putative coding regions, of which 2990 hits were non redundant. An ab initio prediction of coding regions resulted in the compilation of 101,361 hits in exon regions of the 47,706 scaffolds evaluated.

Using a minimum 15X average coverage as a cut off, a total of 1300 perfect microsatellite sites were selected in functional and structural genomic regions of sour passion fruit. In this sample of microsatellite sites, tri-nucleotide repeats were the most abundant class (534 sites), followed by tetra-nucleotide (475) and di-nucleotide (294) (Fig. 1a). The most frequent types of microsatellite sequences observed on each class were AT/TA, GAA/TTC and AAAT/ATTT (Fig. 1b). The most frequent di-nucleotide repeat motif (AT) was also the most abundant one, comprising (5.3%) of the perfect microsatellite region detected on contigs with at least 15X coverage. On the

**Table 2** Summary of Illumina paired-end read sequence data, de novo assembly and detection of microsatellite repeats in the *Passiflora edulis* genome

Sequence information	Total #	Size variation (bp)	Average length (bp)	Total (bp)
Illumina paired-end reads	225,293,527	52–76	62.65	14,113,860,125
Contigs	234,239	166–45,662	707	165,702,691
Microsatellite sequences	Total #	>5 repeats		
Compound and/or imperfect microsatellites	1,544,549	-		
Perfect di-nucleotides	360,162	13,391		
Perfect tri-nucleotides	60,669	1436		
Perfect tetra-nucleotides	7463	186		
Total	1,972,843	-		

other hand, tri- and tetra-nucleotide repeat motifs had a more balanced distribution among different classes.

The list of 1300 microsatellite sites was further examined for PCR primer development (Additional file 1). Primer pairs flanking the DNA repeats could be developed for 816 microsatellite sites, which were suitable for design within each contig, showing no adjacent simple sequence repeat loci and attending the minimal specified requirements which have been previously

described. The new microsatellite markers were given the “BrPe” prefix. The list includes 149 di-, 329 tri- and 338 tetra-nucleotide markers. Approximately 56% of the markers are located in functional regions of the *P. edulis* genome (60 di-, 263 tri- and 139 tetra-nucleotide markers) and the remaining in structural regions.

A random sample of 60 markers (50 di- and 10 tri-nucleotide repeats) was labeled with fluorescent dyes and combined for simultaneous amplification in duos or

trios in order to test their genotyping efficiency and marker polymorphism on passion fruit accessions. We tested 25 panels, usually containing two markers each, for simultaneous allele amplification. A total of 52 markers could readily amplify PCR products in all 25 duo panels without any adjustment in PCR amplification conditions (Fig. 2). Five markers worked better in solo amplifications (BrPe0014, BrPe0021, BrPe0033, BrPe0042, BrPe0043). PCR amplicons were not obtained for only three markers (5%) (BrPe0004, BrPe0005, BrPe0048), although further attempts to adjust PCR were not pursued. This represents a very high rate of PCR amplification success for microsatellite markers.

#### Descriptive statistics of microsatellite markers

Among the 57 markers which produced amplicons, 42 (~74%) were polymorphic when tested on a sample of ten *P. edulis* germplasm accessions, providing the detection of 137 alleles (Table 3). Fifteen markers were not polymorphic (nine di-nucleotide and six tri-nucleotide repeat markers) (Additional file 1). The number of observed alleles for all polymorphic microsatellite markers ranged from 2 to 7, with an average value of 3.26 alleles per locus (Table 3). Marker expected heterozygosity ( $H_e$ ) values ranged from 0.19 to 0.84, with an average of 0.55. Observed heterozygosity ( $H_o$ ) values ranged from 0.00 to 1.00, with an average of 0.35. Polymorphism Information Content (PIC) values ranged from 0.16 to 0.77, with an average of 0.45 (Table 3).

We checked whether the size ranges for the polymorphic loci included their expected product size on *P. edulis*. Expected product sizes for each microsatellite marker are based on sequence information generated by the de novo assembly process. The proportion of markers

that generated amplicons within 5% of their expected sizes was 100% (42 out of 42). Approximately 55% of the polymorphic markers generated amplicons with product size exactly as expected (23 out of 42).

Out of 50 di-nucleotide markers tested for DNA polymorphism, 17 were located on structural genomic regions and 33 on putative functional sites of the *P. edulis* genome (Additional file 1). We found no significant association (Fisher's exact test  $p$ -value = 0.64) between the level of marker polymorphism and repeat size (di- or tri-nucleotide).

Microsatellite marker cross-amplification in *Passiflora* species.

Markers were ranked by PIC values and used to evaluate their cross amplification in 79 *Passiflora* species (including *P. edulis*). The average PIC value for the 18 selected markers was 0.60, varying from 0.46 to 0.77 (Table 3, markers 1–16, 18, 19). A survey on the potential cross-amplification of these microsatellite markers in a collection of *Passiflora* species showed that 72% of the marker/species combinations resulted in positive amplifications (Table 4), with cross-amplification values ranging from 33% to 94%. Such a large proportion of marker transferability was not anticipated. Three markers produced PCR products in all 79 *Passiflora* species (BrPe0032, BrPe0038, BrPe3011). BrPe0032 had the highest PIC and number of alleles in the tested sample of *P. edulis* accessions. Primers BrPe0001, BrPe0034 and BrPe0042 also worked in most of the species tested, with the exception of *P. porophylla* (BrPe0001), *Passiflora triloba* and *P. vitifolia* (BrPe0034), and *P. capsularis* and *P. gibertii* (BrPe0042). Interestingly, at least 14 markers (BrPe0032, BrPe0038, BrPe3011, BrPe0001, BrPe0034, BrPe0042, BrPe0036, BrPe0006, BrPe0010, BrPe0028,

F: forward primer; R: reverse primer; T<sub>a</sub>: annealing temperature; Ho: observed heterozygosity; He: expected heterozygosity; PIC: polymorphic information content

BrPe0031, BrPe0021, BrPe0003, BrPe0033) could cross amplify PCR products in 17 species (*P. cerasina*, *P. coccinea*, *P. decaisneana*, *P. quadrangularis*, *P. riparia*, *P. variolata*, *P. mendoncaei*, *P. nitida*, *P. racemosa*, *P. recurva*, *P. ligularis*, *P. maliformis*, *P. odontophylla*, *P. pedata*, *P. tenuifila*, *P. alata*, *P. setacea*). Fifty percent of the markers produced amplicons in all but two of the species tested, *P. pohlii* (*Decaloba*) and *P. sclerophylla* (*Astropheia*).

The new microsatellite markers uncovered genetic diversity in *P. edulis* (Fig. 2, Table 3) and also in other related species (Fig. 3). PCoA analysis based on marker polymorphism assessed by 18 markers on 28 accessions belonging to six species (*P. edulis*, *P. alata*, *P. maliformis*, *P. nitida*, *P. quadrangularis* and *P. setacea*) allowed their separation in four main clusters. The variation captured by eigenvalue of the first three axis was high (axis 1 = 32.08%, axis 2 = 14.20% and axis 3 = 11.10%). Interestingly, the *P. edulis* accessions formed two clusters

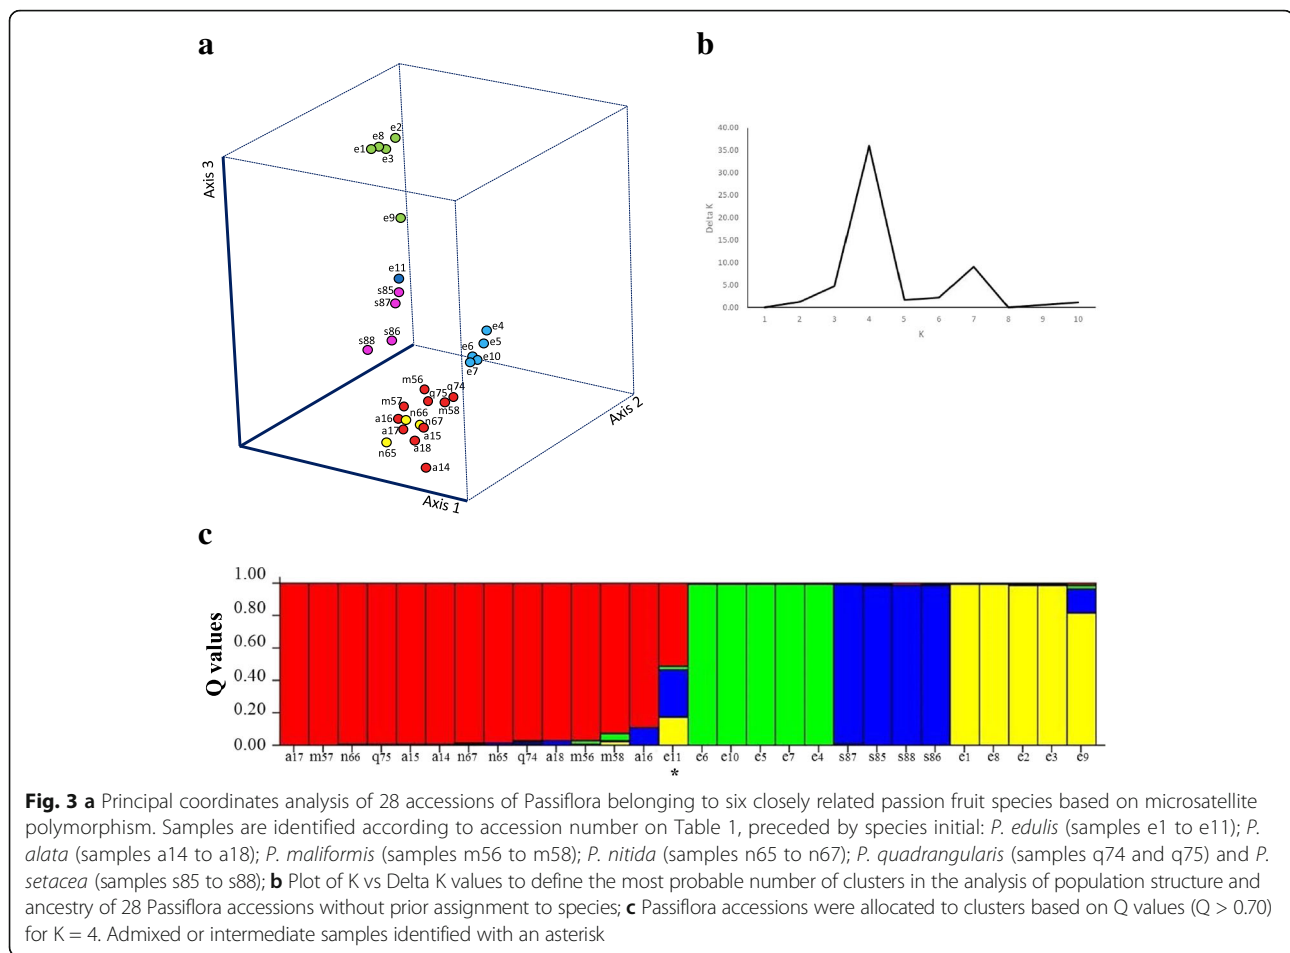

(Fig. 3a) and could be easily separated from the accessions of the other *Passiflora* species. The only exception was BRS Maracujá Jaboticaba (Table 1, accession 11), which did not cluster with the two *P. edulis* groups and seems to be closely associated to a cluster formed by *P. setacea* accessions. The fourth cluster included accessions of *P. nitida*, *P. quadrangularis*, *P. alata* and *P. maliformis*. Although the accessions of these four species could be discriminated with this set of microsatellite markers, they were all included in the same cluster. An analysis of population structure and ancestry of these 28 accessions with no prior assignment of species also inferred the existence of four main clusters, estimated by plotting values of K vs Delta K, for K varying from 1 to 10 (Fig. 3b). Again the accessions of *P. edulis* were allocated to two clusters, *P. setacea* accessions were separated in a third group, while accessions of *P. nitida*, *P. quadrangularis*, *P. alata* and *P. maliformis* formed a fourth group. All accessions were allocated to one of the

four clusters with  $Q$  value  $\geq 70$ , with the exception of BRS Maracujá Jaboticaba (accession e11), which showed an admixed or intermediate profile.

## Discussion

Most microsatellite markers of *P. edulis* and other *Passiflora* species developed so far were obtained by sequencing of genomic libraries enriched with simple sequence repeat regions [17–19, 23, 30–32]. There are only ~200 microsatellite di-nucleotide markers available for *P. edulis* [17, 19, 23]. Here we describe the efficient use of NGS to obtain a large amount of sequence data and applied bioinformatics tools to develop a novel sample of 816 microsatellite markers for this species. The lack of a significant set of polymorphic microsatellite markers for *P. edulis* and the majority of the *Passiflora* species was one of the main justifications of the present study. Microsatellite marker technology is used routinely in many genetic and breeding applications in different organisms, but it has had very limited use in passion fruit research. Other marker technologies, such as Single Nucleotide Polymorphism (SNP),

have recently become accessible to several plant species and should soon be also available for sour passion fruit.

It has been observed that most microsatellite markers developed for *P. edulis* usually detect low polymorphism, estimated as varying from 15% [19] to 24.7% [23]. These results have been interpreted as evidence that genetic diversity in *P. edulis* is low [18, 19], contrasting with the high morphological [7] and agronomic diversity [8, 10] observed in this species. In order to verify how polymorphic is the new set of microsatellite markers, we tested a random sample of 60 new markers on ten accessions of *P. edulis* collected in different regions of Brazil and estimated genetic parameters such as  $H_o$ , PIC and number of alleles. Approximately 74% of the di- and tri-nucleotide markers with amplicon products were polymorphic, and PIC,  $H_o$  and allele number were high. PIC values for 80.9% (38/47) of the di-nucleotides markers ranged from 0.26 to 0.77, and for 40% (4/10) of the tri-nucleotides markers from 0.30 to 0.50. Using DNA fingerprinting based on only two markers (BrPe0028 and BrPe0032), one could discriminate all *P. edulis* accessions used in the present study. These estimates are similar to values found for other allogamous species

where NGS technology was used for microsatellite development, such as the forage *Brachiaria ruziziensis* [39] or radish *Raphanus sativus* [58]. Therefore, we did not find evidence of low microsatellite polymorphism in *P. edulis* as assessed by the new set of microsatellite markers. Quite contrary, the majority of the markers tested were highly polymorphic. It is possible that the low polymorphism in *P. edulis* assessed by previous studies with microsatellite markers was actually caused by hidden genetic relatedness of passion fruit samples used in the screening, or simply because the markers tested were located in more conserved regions of the sour passion fruit genome.

Perfect microsatellite markers represent only a small fraction (~10%) of the total number of *P. edulis* markers available so far. The vast majority are compound or imperfect motif markers, which are hard to interpret on routine genotyping assays due to allele binning difficulties [26, 27]. Also, most of the studies with *P. edulis* microsatellite markers were based on allelic discrimination in agarose gels [59, 60] or polyacrylamide gels [16, 17, 19, 61, 62], what added more challenge to the analysis of compound and imperfect microsatellite markers. This could be a constraint to some applications, especially for population genetic studies [28]. All new markers are based on repeat of the same nucleotide motif without interruption or variation, what should facilitate genetic analysis.

We tested the new set of *P. edulis* microsatellite markers on other 78 *Passiflora* species. The percentage of cross-species transferability to other species of the subgenus *Passiflora* was high (75.4%), similar to *Distephana* (71.11%). However, it decreased to species belonging to *Astrophea* (63.33) and *Decaloba* (59.72%). Oliveira et al. [24] obtained similar results for cross-species transferability of *P. edulis* microsatellite markers to subgenera *Passiflora* (>73%) and *Decaloba* (54%). It is interesting to notice that *P. edulis* PCR products were obtained for at least 50% of the tested markers in all 90 accessions of other *Passiflora* species, with the exception of *P. pohlii* (*Decaloba*) and *P. sclerophylla* (*Astrophea*). This is an indication that a substantial proportion of the new *P. edulis* microsatellite markers can potentially be used in genetic studies of a great range of *Passiflora* species.

A combined analysis of 28 germplasm accessions of six *Passiflora* species (*P. edulis*, *P. alata*, *P. maliformis*, *P. nitida*, *P. quadrangularis* and *P. setacea*) using the new microsatellite markers demonstrated their efficiency to uncover genetic diversity in passion fruit. *P. edulis* accessions formed two clusters that could be easily separated from the accessions of the other *Passiflora* species. These *P. edulis* accessions were obtained in different regions of Brazil but there was no correlation between genetic clustering and geographic origin (data not

shown). One of the clusters, however, is comprised of sour passion fruit accessions (Table 1, accessions 1–3 and 8) that have been widely used commercially (ex. accessions Maguary, CPGA1 and CPMSC1) and possibly derived from population of common ancestry [23]. Accession 8 (Criciúma, Santa Catarina) was originally collected in area close to *Passiflora* orchards, and its fruits might have been derived from cross-pollination with commercial cultivars. Although classified as *P. edulis*, the accession BRS Maracujá Jaboticaba (Table 1, accession 11) did not cluster with accessions of the two *P. edulis* groups. BRS Maracujá Jaboticaba seems to be closely associated to a third cluster formed by *P. setacea* accessions (Fig. 3a), although the estimated probability of inclusion in this group was not high (Q value = 0.52) (Fig. 3c). Recent analysis of the BRS Maracujá Jaboticaba mating system indicates that this accession is preferentially autogamous, while most *P. edulis* accessions are allogamous [63], what could explain its genetic distance to other sour passion fruit accessions. Further analysis on the role of different mating systems and mating plasticity in *P. edulis* genetic diversity should be pursued.

The fourth cluster included accessions of *P. nitida*, *P. quadrangularis*, *P. alata* and *P. maliformis*. Molecular phylogeny analysis of *Passiflora* species using nrITS, trnL-trnF and rps4 polymorphism grouped *P. alata*, *P. quadrangularis*, *P. maliformis*, *P. setacea* and *P. edulis* [64]. Plastid DNA analysis also found that *P. alata*, *P. nitida*, *P. edulis* and *P. maliformis* are closely related [65]. Paiva et al. [60] using microsatellites markers of Oliveira [23] and Pádua et al. [31] identified molecular similarity among *P. edulis* and *P. setacea*. *Passiflora* phylogeny is indeed very complex, with more than 520 species distributed in several continents. Microsatellite markers might help to understand genetic relationships within species and among accessions of closely related species.

Anthropic pressure at the centers of diversity is contributing to genetic erosion of many plant species, including *Passiflora* [66–68]. Intensive in situ conservation of native flora as well as efforts to collect wild species, landraces and local varieties for ex situ conservation are necessary for current and future use of passion fruit. Short term seed viability remains an important constraint to conservation [69, 70] and most collections rely on vegetative propagation for storage. It is a challenge to keep large numbers of passion fruit accessions by vegetative propagation of germplasm collections with usually restricted human and economic resources. Since vegetative propagation is the main form of conservation, each accession of passion fruit is usually comprised of one or a few plants per species or variety, imposing limits to ex situ genetic diversity storage. Routine activities of germplasm conservation and breeding demand the application of

genome technology, including microsatellite markers, in conservation and use of passion fruit genetic resources.

## Conclusion

NGS technology was used to obtain a large amount of sequence data, which was applied to the development of hundreds of microsatellite markers for *P. edulis*. The new markers detected high levels of DNA polymorphism in *P. edulis* and could be used to assess genetic diversity in sour passion fruit accessions and in closely related species. The levels of cross-species transferability varied from 33% to 89% after testing 78 *Passiflora* species belonging to four subgenera (*Passiflora*, *Distephana*, *Astrophea* and *Decaloba*), indicating that a great number of *P. edulis* microsatellite markers could be potentially used in genetic analysis of other *Passiflora* species. This new set of microsatellite markers has many applications to germplasm conservation, breeding programs and genetic studies of passion fruit.

## Acknowledgements

We would like to thank CAPES for a partial scholarship to SA. This research was also supported by CNPq, Rede Passitec, Embrapa Cerrados and Embrapa Genetic Resources and Biotechnology.

## Funding

The design of the study, collection, analysis, and interpretation of data and manuscript writing were sponsored by Embrapa Macroprograma 2 (Grant # 02.12.02.006.00.03) and Rede Passitec II (CNPq 404,847/2012–9). A partial Ph.D. scholarship was provided by CAPES to SA.

## Availability of data and materials

Information about contigs, repeat motifs, primer sequences, melting temperatures and expected product sizes for 816 di-, tri- and tetra-nucleotide microsatellite markers is available on Additional file 1.

## Authors' contributions

SA worked on DNA extraction, primer design, multiplex panel development, marker genotyping, statistical analyses and drafted the manuscript. AMM prepared genomic libraries, worked on genome assembly and detection of microsatellite sequences. AMC helped with the discussion. NTJ helped to identify and collect all the accessions. FGF supervised the study and helped with the discussion. MEF conceived the study, supervised the laboratory

work, performed statistical analyses and drafted the manuscript. All authors read and approved the final manuscript.

## Ethics approval and consent to participate

This study has been conducted in accordance with the Brazilian legislation (Law 13.123–5/2015) and the "Convention on the Trade in Endangered Species of Wild Fauna and Flora". All plant accessions used in the study are deposited at and maintained by the "Flor da Paixão" Passion Fruit Germplasm Bank, Embrapa Cerrados (CPAC), BR 020 Km 18, Planaltina, DF, 73.310–970, Brazil. The Passion Fruit Germplasm Bank was established by resolution n° 041/2011/SECEX/CGEN, Process n° 02000.001723/2010–31, Genetic Heritage Management Council (CGEN). The authorizations for conducting scientific research and bio-prospection were provided by the Brazilian Institute of the Environment and Renewable Natural Resources (Special Authorization n° 002/2008, Process N° 02001.008153/2009–67) and CGEN (Special Authorization n° 001-B/2013, Process n° 02000.001704/2009–71). Voucher specimens of the plant accessions used in the present work have been deposited at the Embrapa Genetic Resources and Biotechnology Herbarium, Brasília, DF, Brazil. The experimental research described here comply with institutional, national, and international guidelines. Seeds and cuttings can be available by request.

Submit your next manuscript to BioMed Central and we will help you at every step:

- We accept pre-submission inquiries
- Our selector tool helps you to find the most relevant journal
- We provide round the clock customer support
- Convenient online submission
- Thorough peer review
- Inclusion in PubMed and all major indexing services
- Maximum visibility for your research

Submit your manuscript at  
[www.biomedcentral.com/submit](http://www.biomedcentral.com/submit)
