ABSTRACT

Introduction: Transdermal cannabinoids may provide better safety and bioavailability profiles compared with other routes of administration. This single-arm, open-label study investigated a novel topical transdermal delivery system on the pharmacokinetics of cannabidiol (CBD) and tetrahydrocannabinol (THC).

Methods: Participants were 39.5 ± 7.37 years old and healthy, based on a review by the Medical Director. Blood was collected pre-dose and 10, 20, 30, and 45 min, and 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, and 12 h after topical application of 100 mg CBD:100 mg THC. Psychoactive effects were assessed prior to each timepoint. Area-under-the-curve ($AUC_{0-12\text{ h}}$), maximum concentration (C_{\max}), time to maximum concentration (T_{\max}), area-under-the-curve to infinity (AUC_{∞}), terminal elimination rate constant (λ), terminal half-life ($t_{1/2}$), and absorption rate constant (k_a) were measured individually for

CBD and THC. Safety was assessed by clinical chemistry, hematology, and adverse events.

Results: $AUC_{0-12\text{ h}}$ for CBD and THC was 3329.8 ± 3252.1 and 2093.4 ± 2090.6 pg/mL/h, with C_{\max} of 576.52 ± 1016.18 and 346.57 ± 776.85 pg/mL, respectively. T_{\max} for CBD and THC was 8 h, ranging from 2.5 h to 12 h and 10 min to 12 h, respectively. AUC_{∞} for CBD and THC was 6609.2 ± 7056.4 and 3721.0 ± 3251.7 pg/mL/h, with $t_{1/2}$ of 5.68 ± 1.5 and 5.38 ± 1.25 h, respectively. CBD was absorbed at a faster rate compared with THC (123.36 ± 530.97 versus 71.5 ± 1142.19 h⁻¹) but with similar λ (0.12 ± 0.029 versus 0.13 ± 0.03 h⁻¹). No psychoactive effects were reported. Transdermal cannabinoid delivery was safe and well tolerated in the population studied.

Conclusion: To our knowledge, this is the first pharmacokinetic study in humans that demonstrated CBD and THC entering systemic circulation via transdermal administration. This study represents an important contribution to understanding the pharmacokinetics of transdermal cannabinoids.

Clinical Trial Registration: ClinicalTrials.gov Identifier—NCT05121506 (November 16, 2021).

Key Summary Points

Why carry out this study?

Transdermal administration of cannabinoids may provide safety and bioavailability advantages over other routes of administration.

There is no previous literature on transdermal cannabinoid pharmacokinetics.

What was learned from this study?

The investigated technology delivering CBD and THC was found to be safe and well tolerated, with no associated psychoactive effects.

There was large variability in the pharmacokinetics of CBD and THC between individuals when delivered transdermally.

Future double-blind, randomized, placebo-controlled pharmacokinetic studies are needed to confirm the preliminary findings of this open-label, exploratory study.

INTRODUCTION

Transdermal delivery of cannabinoids may provide advantages over other more traditional routes of administration. Rapid entry of cannabinoids into systemic circulation via inhalation involves risks related to toxicity and exposure to carcinogenic byproducts [1], and oral consumption can lead to a greater likelihood of overconsumption [2]. It has been suggested that transdermal cannabinoids may provide diminished psychotropic effects and more constant cannabinoid plasma levels [3, 4], benefiting those with certain medical conditions and individual lifestyles. However, transdermal cannabinoid delivery is challenging. Cannabinoids are hydrophobic molecules,

which prevents them from easily diffusing through the aqueous layer of the skin [5]. In general, cannabinoids are molecules that have low transdermal uptake, build up in a reservoir in the stratum corneum (outermost layer of the skin), and thought not to reach the blood [6]. To our knowledge, there are no published studies in humans that have demonstrated that cannabinoids can enter systemic circulation via transdermal administration.

The objective of this study was to investigate the systemic bioavailability of cannabidiol (CBD) and tetrahydrocannabinol (THC) following acute topical administration using Gefion GT4 technology, a novel transdermal delivery system, in a single-arm, open-label study of 18 healthy adults.

METHODS

Ethical Approval and Trial Registration

This study was conducted at KGK Science Inc. (London, Canada) from November 2021 to January 2022, and approved by the Therapeutic Products Directorate (TPD) (Health Canada, Ottawa, Canada), and the Institutional Review Board Services (Aurora, Canada) (Pro00058904). The study was conducted in accordance with the 1964 Declaration of Helsinki guidelines and its subsequent amendments, and in compliance with the International Council for Harmonization of Technical Requirements for Pharmaceuticals for Human Use Guideline for Good Clinical Practice. The trial was registered at Clinicaltrials.gov (NCT05121506). Participants provided written informed consent before the initiation of study procedures.

Study Procedures

Participants attended a screening visit and a 12-h in-clinic visit. A follow-up phone call assessed adverse events (AEs) for up to 1 week after product administration. At screening, current health status, concomitant medications, medical history, and inclusion/exclusion criteria were reviewed. Height, weight, heart

rate (HR), and blood pressure (BP) were measured, and urine tests determined pregnancy status (females only) and the presence of drugs of abuse. The health of participants was assessed by blood collected for clinical chemistry, hematology, hemoglobin A1c (HbA1c), human immunodeficiency virus (HIV), and hepatitis B/C. Eighteen eligible participants (nine female, nine male) returned to the clinic. Urine tests confirmed pregnancy status and presence of drugs of abuse, vital signs were measured, and body mass index (BMI) calculated. Participants washed their left hand, wrist, and forearm with soap and water within 30 min of topical administration, and immediately before application the area was wiped with alcohol disinfectant. Study personnel rubbed a topical dose of 100 mg CBD and 100 mg THC into the left hand, wrist, and forearm until absorbed (approximately 90 s) and the timing of scheduled blood draws was dependent on the time of complete absorption. Blood was collected pre-dose ($t = 0$) and at 12-h post-dose for safety analysis of clinical chemistry and hematology. Blood was collected pre-dose ($t = 0$) and at 10, 20, 30, 45 min, and 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, and 12 h after cannabinoid administration for analysis of CBD and THC concentrations in plasma. Psychoactive assessments were conducted immediately before each post-dose blood draw timepoint. Participants were asked “Are you experiencing a ‘high’ feeling?” and their answer determined whether they were subsequently asked “On a scale of 1 (least) to 10 (most), how intense is that feeling?” and “Is this ‘high’ feeling (other than intensity) different than past high experiences? If yes, please describe.”

Participants

Participants were included if they were between the ages of 25–65 years, met study criteria for contraception; had a BMI between 18.5 and 29.9 kg/m²; consumed cannabis at least once in the past 6 months, but not more than three times per week, without experiencing severe AEs; agreed to washout of cannabis and tobacco/nicotine products 48 and 96 h prior to

dosing, respectively; and were determined by the Medical Director (MD) as healthy, via medical history and laboratory results.

Individuals were excluded if they were pregnant, breast feeding, or planning to become pregnant; were a habitual user of cannabis (≥ 4 times/week); had an acute or chronic skin disease or dermatological condition on the proposed area of application; had shaving, waxing, or laser hair removal on the proposed area of application within 14 days of dosing; were positive for drugs of abuse at screening or baseline; self-reported serious psychological disorder(s) diagnosis or had an immediate family member with a history of psychosis; used prescription or over-the-counter medications or supplements that may have affected study results or participant safety; or clinically significant abnormal laboratory results or recent or active unstable medical condition that may have adversely affected their ability to fully participate in the study or posed significant risk, as assessed by the QI.

Investigational Product

The investigational product (IP) was a novel Gefion GT4 technology that used emulsion technology containing penetrating agents, basement membrane disruptors, and vasodilators to overcome hydrophilic and lipophilic structures to open channels and transport cannabinoids deep into the dermis layer of the skin [7]. Once in the dermis, vasodilators dilate the capillary bed to increase fluid dynamic flow into and out of the application site, delivering cannabinoids into the blood stream [7]. The Gefion GT4 transdermal delivery system has been used previously to deliver gabapentin and naproxen sodium for the treatment of pain, with meaningful efficacy and no reported AEs (H. Crowley, personal communication, 16 June 2019).

Laboratory Analyses

Blood collected for CBD and THC analysis was centrifuged immediately for 10 min at 1500g at 4 °C. An aliquot of 1 mL of plasma was

separated into three cryogenic vials and stored at -80°C until being shipped for analysis. An aliquot of $300\ \mu\text{L}$ of human plasma was used for the analysis of CBD and THC by Altasciences Company Inc. (Laval, Canada). The compounds were identified and quantified using reverse-phase high performance liquid chromatography (HPLC) with triple quadrupole mass spectrometry (LC-MS/MS API 6500) and an injection volume of $10\ \mu\text{L}$. The detection limits were $25.0\text{--}7500.0\ \text{pg/mL}$ for CBD and $50.0\text{--}30,000.0\ \text{pg/mL}$ for THC. Screening blood work and safety endpoints were analyzed by LifeLabs (London, Canada) using standard procedures. Urine pregnancy tests for females of childbearing potential and drugs of abuse analysis was conducted at KGK Science (London, Canada).

Statistical Analysis

The pharmacokinetic (PK) outcomes for CBD and THC were evaluated for intention-to-treat (ITT) and per protocol (PP) populations. The ITT population consisted of all participants who received the IP, and on whom any PK information was available. The PP population consisted of all participants who received IP, did not have any major protocol violations, and completed all study visits and procedures connected with measurement of primary outcomes.

PK outcomes included: area under the curve over a 12-h period ($\text{AUC}_{0-12\ \text{h}}$); area under the curve to infinity (AUC_{∞}); time to maximum concentration (t_{max}); peak concentration (C_{max}); terminal elimination rate constant (λ); terminal half-life ($t_{1/2}$); and absorption rate constant (k_a). $\text{AUC}_{0-12\ \text{h}}$ was calculated using the trapezoid approximation. C_{max} and T_{max} were determined directly from the concentration–time curve. AUC_{∞} was calculated by $\text{AUC}_{0-12\ \text{h}} + \text{CT}/\lambda$, where CT was the last quantifiable concentration. λ was calculated as the slope of points on the terminal log-linear end of the concentration versus time curve. $t_{1/2}$ was calculated as $\ln(2)/\lambda = 0.693/\lambda$ and k_a was calculated using the feathering method. Psychoactive assessment data was summarized using descriptive statistics (means, standard

deviations, medians, minimums, maximums). All data is presented as mean \pm standard deviation.

RESULTS

Participants

A total of 30 potential participants were screened and 18 participants were enrolled in this study. Enrolled participants completed all study procedures (Fig. 1).

Participants were an average of 39.5 ± 7.37 years old, with 89% of the population Eastern/Western European White. The average BMI of participants was slightly overweight ($25.95 \pm 2.35\ \text{kg/m}^2$), with 39% classified as normal weight ($< 25\ \text{kg/m}^2$) and 61% classified as overweight ($\geq 25\ \text{kg/m}^2$) (Table 1).

Four participants were removed from the PP analysis due to detectable cannabinoids pre-dose and one participant was removed due to concentration values exceeding the upper limit of quantification at 10 min post-dose. This single participant was excluded from the PP population after their samples were diluted and analyses repeated for accuracy, as verified by Altasciences Company Inc.

Pharmacokinetic Outcomes

In the PP population, $\text{AUC}_{0-12\ \text{h}}$ for CBD and THC was 3329.8 ± 3252.1 and $2093.4 \pm 2090.6\ \text{pg/mL/h}$, respectively, with C_{max} of 576.52 ± 1016.18 and $346.57 \pm 776.85\ \text{pg/mL}$. The T_{max} for CBD and THC was 8 h, with T_{max} ranging from 2.5 to 12 h and 10 min to 12 h, respectively. At 12-h post-dose, concentrations of CBD and THC had not returned to pre-dose levels, demonstrating that the blood sampling period was not long enough to capture the entire PK curve. AUC_{∞} for CBD and THC was 6609.2 ± 7056.4 and $3721.0 \pm 3251.7\ \text{pg/mL/h}$, respectively, with comparable $t_{1/2}$ of 5.68 ± 1.5 and $5.38 \pm 1.25\ \text{h}$. CBD was absorbed at a faster rate compared with THC (123.36 ± 530.97 versus $71.5 \pm 1142.19\ \text{h}^{-1}$) but with similar λ

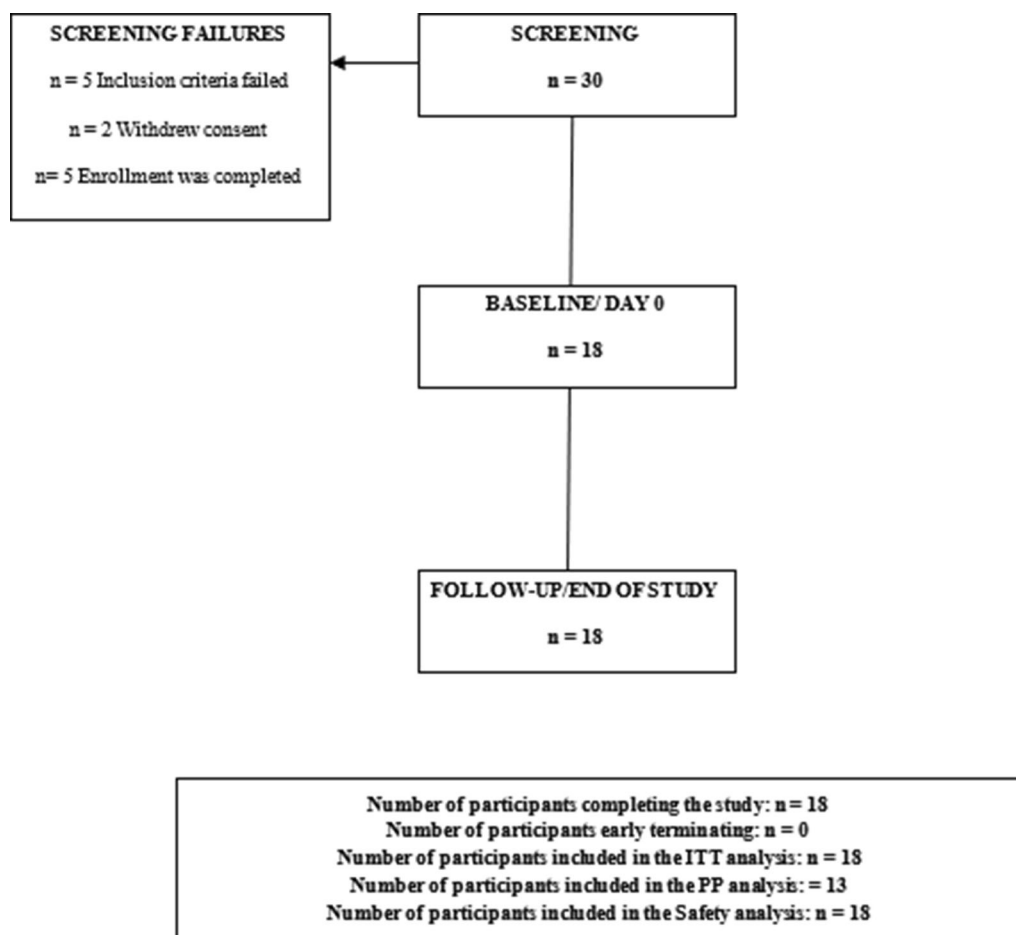

Fig. 1 Disposition of study participants

(0.12 ± 0.029 versus $0.13 \pm 0.03 \text{ h}^{-1}$) (Fig. 2). PK outcomes for the ITT population can be found in Tables S1 and S2. Individual time-concentration curves are provided in Figs. S1–S18.

Psychoactive Assessment

None of the participants in ITT population reported feeling psychoactive effects at any post-dose blood draw timepoint. One hundred percent of participants responded to “Are you experiencing a ‘high’ feeling?” with “No” and therefore were not asked the remaining psychoactive assessment questions.

Safety

There were two post-emergent AEs reported by two participants, each reporting a headache following dosing. The post-emergent AEs were classified as mild in intensity and unrelated to the IP. One participant recovered on the same day as IP administration, and the other had recovered by the following day. No AEs were reported in the 7 days following cannabinoid delivery. There were no statistically significant or clinically relevant changes in clinical chemistry or hematology parameters, as confirmed by the MD.

Table 1 Demographics, anthropometric measurements, and substance use for participants in the ITT population (*n* = 18)

Characteristic	Levels	Baseline
Age, years	Mean ± SD	39.5 ± 7.37
	Median (min–max)	41 (27–57)
	(<i>n</i>)	(<i>n</i> = 18)

DISCUSSION

Transdermal delivery of cannabinoids may provide advantages over other more traditional routes of administration. Cannabis smoking rapidly yields very high concentrations of cannabinoids in the bloodstream, but comes with risks associated with toxicity, exposure to carcinogenic byproducts, and respiratory conditions, as well as loss of activity through combustion (inactive and degraded cannabinoids due to excess heat) [1, 8–11]. When consumed orally, cannabinoids undergo first-pass metabolism, resulting in reductions in bioavailability and other unwanted effects associated with liver metabolizing enzymes, most notably, the cytochrome P450 system [12]. THC metabolism via cytochrome P450 (CYP450) produces a greater accumulation of 11-hydroxytetrahydrocannabinol, a potent, longer-lasting psychoactive metabolite that that may go beyond the desired effects of a novice or medical consumer [12]. Furthermore, CBD metabolism by CYP450 is associated with potentially dangerous drug–drug interactions that may be minimized when CBD is delivered through the skin, owing to delayed cannabinoid accumulation [13]. This can be particularly important in the treatment of chronic conditions over long periods of time or where a treatment regimen involves significant quantities of CBD as it relates to the patient’s body weight, for example in pediatrics. It is suggested that by avoiding first-pass metabolism and applying cannabinoids to the skin, psychotropic impacts may be reduced, and

Fig. 2 Mean time-concentration curves for CBD and THC over the 12-h blood sampling period for participants in the PP population ($n = 13$)

more constant cannabinoid plasma levels can be achieved [3, 4]. A challenge with transdermal delivery is that cannabinoids are hydrophobic molecules, preventing them from easily diffusing through the aqueous layer of the skin [5]. In general, cannabinoids are molecules that have low transdermal uptake, build up in a reservoir in the stratum corneum, and thought not to reach the blood [6]. Using emulsion technology containing penetrating agents, basement membrane disruptors, and vasodilators, Gefion GT4 technology targets hydrophilic and

lipophilic structures to open channels and transport cannabinoids deep into the dermis layer of the skin, while vasodilators dilate the capillary bed to increase fluid dynamic flow to deliver cannabinoids into the blood stream [7].

To our knowledge, this is the first PK study that has demonstrated the ability of CBD and THC to successfully enter systemic circulation via transdermal administration in humans. Importantly, the successful delivery of cannabinoids via Gefion GT4 technology was safe and well tolerated by all participants. There

were no clinically significant changes in clinical chemistry or hematology, or any related AEs in the 7-day monitoring period following dosing. This study represents an important step in understanding cannabinoid PKs, opening the door for novel cannabinoid delivery systems, and therapeutic interventions. Previous *in vitro* studies investigating cannabinoid permeability in human skin found that CBD had an approximately $10 \times$ higher permeability than THC [14, 15], aligning with research that determined that CBD is relatively less lipophilic than its psychoactive counterpart [15]. These findings are consistent with the greater AUC and C_{\max} found with CBD in the current study, although to a lesser degree than what has been previously reported [15]. This preliminary data suggests that to deliver equal doses of CBD and THC via the skin, a greater dose of THC may be required. In the current study, T_{\max} for CBD and THC occurred later in the blood sampling period compared to what is expected from other routes of administration. Previous literature has demonstrated that T_{\max} for CBD and THC in inhaled and orally consumed forms occurred within only a few minutes to approximately 4 h post-dose [16–18]. Inhalation provides a faster T_{\max} because of avoidance of the gastrointestinal tract and first-pass metabolism [5, 19]. Given the challenges of transdermal delivery of cannabinoids (hydrophobic molecules required to pass through aqueous layers of the skin) and preclinical research demonstrating a T_{\max} of up to 38 h post-dose [20], it is not surprising that delayed absorption and a longer T_{\max} for CBD and THC was found in this study. Furthermore, transdermal delivery of CBD and THC appeared to result in a smaller C_{\max} than has been found for inhaled and orally consumed cannabis. When occasional cannabis consumers were given a maximal 50.6 mg dose of THC via smoked, vaporized, and ingested routes of administration, C_{\max} was found to be 52, 48, and 10 ng/mL, respectively [19]. In another study of occasional users, administration of only 1.35 mg of CBD in a liquid extract capsule resulted in a C_{\max} of 0.93 ng/mL [21]. Comparatively, in the current study topical application of 100 mg of CBD and THC resulted in a C_{\max} of 576.52 pg/mL (0.576 ng/mL) and 346.57 pg/mL

(0.346 ng/mL), respectively. The C_{\max} of cannabinoids delivered transdermally appear to be lower than that of inhaled or oral routes of administration, despite a higher delivered dose. However, the results of this study need to be considered in the context of large interindividual variation and a blood sampling period that was not sufficient to capture the full descending arm of the PK curve.

For both CBD and THC, there was large interindividual variation across all PK parameters except for $t_{1/2}$ and λ , suggesting that once successfully in the blood stream, the cannabinoids were removed from systemic circulation at similar rates between participants. However, the magnitude and rate at which cannabinoids were able to diffuse through the skin appeared to be highly dependent on the individual participant.

Several reasons may explain the variability found between individual participants in this study. Transdermal drug distribution tends to present in more erratic patterns with less symmetrical bell-shaped curves [22] due to biological differences that affect the structure and integrity of the skin, leading to variation in the quantity absorbed [23–25]. The quality of an individual's skin may be influenced by gender, ethnicity, metabolism, and perhaps most notably, age [23]. As humans get older, the epidermis and dermis layers of the skin begin to thin, and there are critical changes in keratinocytes, melanocytes, type-3 collagen fibers, and Langerhans cells [26]. Changes to aging skin has contributed to significant reductions in skin permeability and drug absorption [23]. However, those that are more lipophilic, such as testosterone and estradiol, were less impacted by aging skin [27]. Considering that participants in the current study ranged in age from 27 to 57 years, the integrity and quality of skin of individual participants may have contributed to large interindividual variation in cannabinoid absorption. Further adding to the large variation may have been differences between males and females, which made up an equal 50% of the enrolled study population. Men typically have larger keratinocytes [28] and sweat and sebaceous glands [29], and a lower skin pH than females [30], which could result in varying

levels of transdermal permeation [23]. Although most studies have not demonstrated any significant differences between males and females in transdermal drug delivery, this previous research should not be generalized to cannabinoids without further investigation. Cannabinoids are highly lipophilic molecules that are readily absorbed into fatty tissues [5, 31] and contain unique molecular structures. Although BMI is a poor predictor of body fat [32], there was a range between 20.6 and 29.1 kg/m² in study participants, suggesting there may have been large variations in body fat percentage. Depending on the amount of body fat, particularly subcutaneous deposits at the application site, body fat may have contributed to the variation in PK parameters since this adipose layer can sequester CBD and THC molecules. This also could account for the PK penetration differential between CBD and THC as THC is substantially more lipophilic.

The findings of this study must be considered in the context of certain limitations. The study design was chosen to provide adequate information on the transdermal delivery of cannabinoids in humans. As this is the first study to demonstrate the PKs of CBD and THC following transdermal application, the length required for blood sampling was unclear. The preliminary results clearly demonstrate that the 12-h sampling period was not sufficient to capture a full PK curve, owing to the delayed rate at which cannabinoids entered the blood stream. Health Canada guidance on the conduct of bioequivalence studies recommends that to accurately estimate PK parameters, a minimum of three timepoints should be collected on the descending arm of the PK curve [33]. In total, 61% (8/13) of participants in the PP population had a T_{\max} of 12 h, indicating that their true T_{\max} may have been 12 h, or any number of hours after that final timepoint. Furthermore, only one participant had their concentration of THC drop to pre-dose levels by the end of blood sampling. In the same vein, the true C_{\max} and AUC for both CBD and THC may have been larger than reported in the current study. Although there was less variability in $t_{1/2}$ and λ among participants, a complete representation of elimination is not possible

without a longer sampling period. Furthermore, this study enrolled a relatively small sample size. The findings of this study will need to be confirmed with a larger double-blind, randomized, placebo-controlled PK trial that utilizes a longer blood sampling period, of at least 48–72 h. Future studies should evaluate differences in transdermal cannabinoid PK profile based on sex, age, and BMI, as well as cannabis use history. Emerging evidence has demonstrated that cannabinoid PKs differ based on years of recreational use, with those reporting more years of use having a greater AUC and C_{\max} , and longer $t_{1/2}$ for major cannabinoids and analytes [34].

The successful delivery of CBD and THC to the blood stream highlights the advantages of transdermal cannabinoid delivery. Although more research is needed, more constant and lower plasma cannabinoid concentrations without concerns of psychoactive effects may be beneficial for certain therapeutic indications and individual lifestyles [3]. The results from the psychoactive assessment suggest that the concentration of THC that reached the brain was not sufficient to produce a feeling of being “high.” In the case of using cannabinoid therapy in the treatment of vulnerable populations, the lower concentration of delivered THC could be viewed as a safety mechanism to prevent psychoactive effects. However, the psychoactive effects of transdermally delivered THC should be explored in isolation from CBD. CBD acts as a negative allosteric modulator to THC and may have diminished the psychoactive effects reported in this trial [35]. Based on the extended delivery of CBD and/or THC demonstrated in this study, the GT4 transdermal delivery system may be more applicable for the treatment of chronic compared with acute conditions that require a more rapid C_{\max} for symptom relief.

CONCLUSIONS

The results of this open-label PK study demonstrated that major cannabinoids CBD and THC can successfully permeate through human skin and enter systemic circulation. Cannabinoid delivery occurred over an extended period of

time, with peak concentration levels occurring later in the blood sampling period. However, these results need to be considered in the context of a 12-h blood sampling period that did not capture the full PK curve and large interindividual variation in the absorption of delivered cannabinoids. Gefion GT4 technology was safe and well tolerated by all participants, with no AEs related to the IP and no clinically relevant changes to clinical chemistry or hematology parameters. Gefion GT4 technology may provide lower, more steady-state cannabinoid concentrations that minimize psychoactive effects in participants. This could represent a significant benefit in the treatment of chronic conditions over longer periods of time, or in the treatment of diseases where high concentrations of cannabinoids are needed in relation to the body weight of vulnerable populations, such as pediatrics. This study represents an important step forward in cannabinoid pharmacokinetics.

ACKNOWLEDGEMENTS

The authors wish to thank our volunteers who participated in this study, and for their compliance to the conduct of the study.

Funding. This study was funded by Gefion Canada, who also funded the journal's Rapid Service Fee and the Open Access Fee for this publication.

Authorship. All named authors meet the International Committee of Medical Journal Editors (ICMJE) criteria for authorship for this article, take responsibility for the integrity of the work as a whole, and have given their approval for this version to be published.

Author contributions. G. Varadi: formal analysis plan, data interpretation; Z. Zhu: conceptualization; H.D. Crowley: study design, data interpretation; M.
