Abstract: Biomethanation is a promising solution to convert H₂ (produced from surplus electricity) and CO₂ to CH₄ by using hydrogenotrophic methanogens. In ex situ biomethanation with mixed cultures, homoacetogens and methanogens compete for H₂/CO₂. We enriched a hydrogenotrophic microbiota on CO₂ and H₂ as sole carbon and energy sources, respectively, to investigate these competing reactions. The microbial community structure and dynamics of bacteria and methanogenic archaea were evaluated through 16S rRNA and *mcrA* gene amplicon sequencing, respectively. Hydrogenotrophic methanogens and homoacetogens were enriched, as acetate was concomitantly produced alongside CH₄. By controlling the media composition, especially changing the reducing agent, the formation of acetate was lowered and grid quality CH₄ (≥97%) was obtained. Formate was identified as an intermediate that was produced and consumed during the bioprocess. Stirring intensities ≥ 1000 rpm were detrimental, probably due to shear force stress. The predominating methanogens belonged to the genera *Methanobacterium* and *Methanoculleus*. The bacterial community was dominated by *Lutispora*. The methanogenic community was stable, whereas the bacterial community was more dynamic. Our results suggest that hydrogenotrophic communities can be steered towards the selective production of CH₄ from H₂/CO₂ by adapting the media composition, the reducing agent and the stirring intensity.

Keywords: power-to-gas; energy storage; biogas upgrading; biomethane; formate; hydrogenotrophic methanogenesis; homoacetogenesis; *Methanobacterium*; *Methanoculleus*

1. Introduction

Renewable energy from wind power and photovoltaics increasingly leads to a temporary excess of electricity that cannot be handled by the grid and traditional storage infrastructure. Hence, technical solutions to store this energy, e.g., in the form of chemical energy carriers, are required. The power-to-gas (P2G) technology converts surplus power into a storable gas [1]. H₂ can be generated through water electrolysis and subsequently injected and stored in the natural gas grid, though with certain limitations [2]. CH₄ can also be produced from excess electricity in a two-stage process: H₂ is first produced through water electrolysis and is then used in a methanation stage to reduce CO₂ to CH₄ [2]. Although the H₂ production technology is quite advanced, it has some drawbacks concerning the long-term storage, safety and low energy density of H₂, as well as the requirement for technical modifications of the natural gas grid. CH₄, on the other hand, is very attractive because the storage and distribution infrastructure is already in place in many countries. CH₄ can be readily injected into the gas grid and has a volumetric energy content of 36 MJ m⁻³, which is more than three times higher than that of H₂ (10.88 MJ m⁻³) [3].

Biogas is the product of anaerobic digestion (AD), which is a well-established commercial process and a key technology in the current and future renewable energy sector [4]. Biogas consists mainly of CH₄ (40–75%) and CO₂ (25–60%) and needs to be upgraded to biomethane by removing CO₂ if injection into the gas grid is intended. Methods for biogas upgrading have been reviewed elsewhere [5–7]. Biological biogas upgrading (biomethanation) uses external H₂ to convert the CO₂ share of the biogas into additional CH₄ via the CO₂-reductive pathway of hydrogenotrophic methanogens. The biomethanation of H₂ is an emerging technology that appears to be advantageous over the catalyst-based chemical methanation (Sabatier reaction) due to its milder reaction conditions [6]. This bioprocess can be performed by pure methanogenic strains [8] or mixed cultures [6]. The latter may have certain economic and process advantages over pure cultures [9].

According to Kougiaris et al. [10] and Rittmann [11], biomethanation of H₂ can be done in three ways: in situ, ex situ and by a hybrid process. In the in situ process, H₂ is injected into the main anaerobic digester or post-digester of a biogas plant to reduce CO₂ and thereby increase the CH₄ content of the biogas. In the ex situ process, biogas or CO₂ reacts with H₂ in a bioreactor that is separate from the AD process. The hybrid process couples partial biogas upgrading in the main AD reactor (in situ) with a final upgrading step in a separate reactor (ex situ). Defining the system to be investigated according to the abovementioned categories is important for comparisons in terms of efficiency and microbiota. An ex situ reactor could provide a defined ecological niche to enrich specialized hydrogenotrophic microbiota with an autotrophic metabolism (methanogenesis and homoacetogenesis). It can be hypothesized that the inoculum, the operation temperature and the continuous supply of H₂ play important roles in shaping the microbial community towards the predominance of either hydrogenotrophic methanogens or homoacetogenic bacteria.

If a complex inoculum is used to perform the ex situ biomethanation of H₂, acetate could be synthesized from H₂ and CO₂ via the Wood–Ljungdahl pathway concomitantly with CH₄ formation. Acetate synthesis during ex situ biomethanation represents a problem, as it is an undesirable carbon and electron sink when CH₄ is the target molecule. It is therefore necessary to manage the microbiota towards selective CH₄ production. In environmental biotechnology, the term microbial resource management implies finding strategies to obtain and maintain a highly performing community [12]. The understanding of metabolic processes in complex communities imposes a great challenge that could be overcome by establishing enrichment cultures to investigate the essential metabolic functions without the need for pure cultures [13]. Enriched mixed cultures could be simple enough to investigate individual community members [14] and represent opportunities to grow uncultivable microbes [15], including those requiring syntrophic partners [16]. Ex situ biomethanation studies have found *Methanobacteriales* [10,17–23], *Methanomicrobiales* [10,24] and *Methanococcales* [24] to be the dominant orders. *Methanothermobacter thermautotrophicus* was the dominant methanogen in three different reactor configurations [10]. In the bacterial domain, *Firmicutes* [10,21,25,26], *Bacteroidetes* [10], *Synergistetes* [21] and *Proteobacteria* [25] were the dominant phyla.

Sludge from biogas reactors or wastewater anaerobic granules has been used as an inoculum source [10,17,19,24,27–31]. From a microbiological point of view, certain process parameters such as temperature and pH, substrate characteristics and inoculum sources define the community structure and dominant members of the microbiota. An ex situ study comparing different reactor configurations reached CH₄ concentrations of more than 98%; however, acetic acid accumulated to concentrations of ~4 g L⁻¹ and the pH values were ≥8 [10]. Similar pH values ranging from seven to ≥8 were also reported in a continuous stirred tank reactor (CSTR) for ex situ biomethanation [32]. Ex situ biomethanation studies have operated at slightly alkaline pH, but microbial enrichment studies under such conditions are still missing.

In the present study, we explore the ex situ biomethanation of H₂ at alkaline pH through an enrichment process. The aim of the enrichment strategy was to better understand the microbial community dynamics assessed by the amplicon sequencing of 16S rRNA and *mcrA* genes to follow the competition between methanogenesis and homoacetogenesis during ex situ biomethanation.

Hydrogenotrophic methanogenesis has been reported as the major methanogenic pathway under high nitrogen load and high ammonia concentration [33–35]. Thus, we used the digestate of a laboratory-scale biogas reactor (CSTR) treating a nitrogen-rich substrate (dried distiller grains with solubles (DDGS)) as the inoculum source for the long-term enrichment of a hydrogenotrophic microbiota that performs *ex situ* biomethanation. Additionally, the effects of media components, such as yeast extract and reducing agent, as well as of the stirring intensity on the H₂ and CO₂ metabolism, were investigated.

2. Materials and Methods

2.1. Inoculum

Anaerobic sludge from a mesophilic (38 °C) laboratory-scale CSTR treating DDGS was sieved using a 400- μ m mesh sieve under nitrogen flow. The liquid inoculum was degassed at 38 °C for 7 days before use. The basic characteristics are the mean values of triplicate measurements as follows: total solids (TS), 3.4%; volatile solids (VS), 70.1%_{TS}; pH, 7.5.

2.2. Growth Medium

Modified mineral medium DSMZ1036 containing yeast extract (0.2 g L⁻¹), as described by Porsch and colleagues [36], was used for the enrichment and is designated as medium A hereafter. For further experiments, the medium was used in two variants: medium B did not contain yeast extract, but was supplemented with a vitamin solution, as described by [37], and cysteine-HCl as reducing agent in the same concentration as in medium A. Medium C contained vitamins, like medium B, but sodium sulfide as a reducing agent, as described by [37]. After preparing the media as described in Text S1 (Supplementary Materials), the pH for all media variations was adjusted to nine with a sterile anoxic stock solution of 2 M KOH.

2.3. Enrichment Setup

Strict anaerobic techniques were thoroughly applied in this study. Sterile anoxic bottles were prepared as described in Text S2 (Supplementary Materials) prior to medium dispensing and inoculation. The gas volume/liquid volume ratio was maintained at three for all experiments, regardless of the size of the bottle, unless stated otherwise. The experiments were conducted with four biological replicates in the first stage (gas feeding of the anaerobic sludge) and triplicates in the second stage (enrichment in the mineral medium). A detailed chronology of the culture transfers is provided in Table S4.

The setup in the first stage was assembled in an anaerobic chamber. Serum bottles of 219.5 mL volume were filled with 50 mL degassed inoculum, sealed with butyl rubber stoppers and crimped with aluminum caps. The gas phase of the serum bottles was replaced by H₂ (80%) and CO₂ (20%). All bottles receiving H₂ and CO₂ were operated in fed-batch mode and pressurized daily to ~2.2 bar for approximately five months. Bottles containing the inoculum and a nitrogen atmosphere (not pressurized) were used as controls to account for the residual biogas production. Detailed information about headspace flushing and pressurization is given in Text S2.

In the second stage, medium A was used to enrich a particle-free culture by six subsequent culture transfers in fresh medium bottles by inoculating the content of the preceding culture transfer (10%, *v/v*). One randomly selected replicate from the first stage served as the inoculum to start the bottles for the second stage. Anoxic medium A (45 mL) was dispensed to sterile, anoxic serum bottles and left overnight in an incubator at 37 °C to reduce any oxygen traces that entered the bottles during medium dispensing. Next, the bottles were inoculated with 5 mL culture from the first stage. Biological controls for determining residual biogas production (containing inoculum but with N₂ gas phase), as well as sterile controls (not inoculated, but with either H₂/CO₂ or N₂ gas phase), were also set up. The bottles were fed with a gaseous substrate, as described above, and incubated at 37.4 °C in an orbital shaking incubator (IKA KS 4000 ic control, IKA®-Werke GmbH & Co. KG, Biberach an der Riss, Germany) at 200 rpm.

2.4. Cultivation Experiments

In a series of four independent experiments, the effects of medium composition and stirring intensity on biomethanation, biomass growth, and production of volatile fatty acids (VFA) were investigated. Experiments were conducted in 1-L pressure-resistant Duran bottles (Schott AG, Mainz, Germany). Bottles were inoculated with 10% (*v/v*) pre-culture (21 days old second stage enrichment culture, 11th transfer (T11)) and incubated at 37 °C under constant orbital shaking at 200 rpm. The experiments were conducted in duplicate and stepwise to investigate the effect of the medium composition (media A, B and C as described in Section 2.2). The gas consumption and production, as well as the development of biomass and VFA production, were frequently monitored.

After the optimal medium had been determined, we tested the effect of the stirring intensity on the CH₄ production and H₂/CO₂ consumption. Instead of shaking, the bottles were stirred with magnetic stirrers (top plate diameter of 145 mm, speed range from 100 to 1400 rpm; Heidolph, Germany) and new magnetic bars (50 mm × 8 mm, LABSOLUTE, Th. Geyer, Renningen, Germany) and incubated at 38 °C. To reduce the detrimental effects of shear forces on the cells, the liquid volume was increased to 500 mL, corresponding to a gas volume/liquid volume ratio of one. The experiments were conducted three times with duplicates (*n* = 6).

Flushing and pressurizing, as well as pressure determination and the sampling of the gas and liquid phases, were done as described above (see also Text S2) for all four experiments.

2.5. Microbial Community Analysis

Samples for community analysis were taken from the inoculum (S), as well as after one month (1 M) and 5 months (5 M) of fed-batch feeding during the first stage of the enrichment. Samples from the second stage were taken at the end of the first (T1), third (T3), and sixth (T6) culture transfer. Liquid samples of 1.5 mL were withdrawn from each bottle with a nitrogen-flushed syringe (Text S2) and centrifuged at 4 °C and 20,817× *g* for 10 min. Pellets were stored at −20 °C until DNA extraction. DNA was extracted with the NucleoSpin[®] Soil Kit (MACHEREY-NAGEL GmbH & Co. KG, Biberach an der Riss, Germany) using SL2 buffer and enhancer solution. The quality and quantity of extracted DNA were verified via gel electrophoresis (0.8% agarose) and photometrically using a NanoDrop ND 1000 spectral photometer (Thermo Fisher Scientific, Waltham, MA, USA). Extracted DNA was stored at −20 °C until use. The microbial community composition was analyzed by the amplicon sequencing of *mcrA* genes for methanogens and 16S rRNA genes for bacteria.

In order to analyze the bacterial communities, the V3–V4 region of the 16S rRNA genes was amplified using the universal primers 341f (5'-CCT ACG GGN GGC WGC AG-3') and 785r (5'-GAC TAC HVG GGT ATC TAA KCC-3') described by Klindworth et al. [38]. For the analysis of the methanogenic communities, the *mls* (5'-GGT GGT GTM GGD TTC ACM CAR TA-3') and *mcrA*-rev (5'-CGT TCA TBG CGT AGT TVG GRT AGT-3') primers were used as described by Steinberg and Regan [39]. All primers contained Illumina MiSeq-specific overhangs. Amplicon libraries were prepared and sequenced on the Illumina MiSeq platform using the MiSeq Reagent Kit v3 with 2 × 300 cycles. Demultiplexed raw sequence data were deposited at the EMBL European Nucleotide Archive (ENA) under the study accession number PRJEB36972 (<http://www.ebi.ac.uk/ena/data/view/PRJEB36972>).

Primer sequences were clipped from demultiplexed and adapter-free reads using Cutadapt v1.18 [40]. Further sequence analysis was performed using QIIME2 v2019.1 [41]. Sequences were trimmed, denoised and merged using the dada2 plugin [42]. For 16S rRNA gene analysis, forward and reverse reads were truncated at 270 bp and 240 bp, respectively. For *mcrA* gene analysis, reads were truncated at 270 bp and 230 bp, respectively. Maximum expected errors were set to two, which is the default value. Chimeras were removed in the default consensus mode of the dada2 plugin. The resulting feature sequences of 16S rRNA gene analysis were classified against the MiDAS (Microbial Database for Activated Sludge) database v2.1 [43], trimmed to the region covered by the 341f and 785r primers. For *mcrA* gene analysis, a taxonomy database was created by using *mcrA* sequences from the RDP (Ribosomal Database Project) FunGene database [44]. For this purpose, *mcrA* sequences

were downloaded (2878 sequences on 21st of January 2019), sequences from uncultured organisms and metagenomic sequences were removed, and taxonomic information was formatted, resulting in 385 sequences used for the classification. As the primer combination 341f/785r also amplifies archaeal 16S rRNA genes, archaeal reads were removed from further analyses of the 16S rRNA genes and bacterial read counts were normalized to 100%.

2.6. Analytical Methods

To determine the TS content of the inoculum, samples were dried at 105 °C for 24 h and the mass was recorded. The TS value was calculated from the mass difference between the fresh and dried sample. Subsequently, the samples were incinerated at 550 °C in a muffle furnace for 2 h and the mass was recorded. The VS value was calculated based on the mass difference between dried and incinerated samples. The mean values of triplicate measurements are presented.

To determine the headspace gas composition, 1 mL gas sample was withdrawn with a syringe and injected into an argon pre-flushed glass vial of 20 mL (Text S2). The gas samples were measured via gas chromatography equipped with an autosampler in a Perkin Elmer GC. The GC was equipped with HayeSep N/Mole Sieve 13X columns and a thermal conductivity detector. The oven and detector temperatures were 60 °C and 200 °C, respectively. The carrier gas was argon. Every gas sample was analyzed immediately or within 24 h after sampling.

The relative pressure in the bottles was measured with a digital manometer (Text S2). The gas amount in the bottles was calculated according to Equation (1). Standard conditions were considered for calculations ($p = 1.01325 \text{ bar}$, $T = 298.15 \text{ K}$). The consumption and production rates of gases (H_2 , CO_2 , and CH_4) were determined from the linear slope of at least three continuous measurements and are given in mmol gas per liter liquid volume per hour ($\text{mmol L}^{-1} \text{ h}^{-1}$).

$$Gas_{(Xi)} [\text{mmol}] = \frac{P_{abs} [\text{mbar}] \times \frac{Gas_{(Xi)} [\%]}{100} \times V_h [\text{mL}]}{R \times T [\text{K}]} \times 1000 \quad (1)$$

where X_i refers to the gas in question, P_{abs} is the absolute pressure inside the bottle, V_h is the headspace volume of the cultivation bottle (169.5 mL), R is the universal gas constant ($8.314 \times 10^4 \text{ mbar cm}^3 \text{ mol}^{-1} \text{ K}^{-1}$), and T is the standard temperature.

For measuring the concentration of VFA (formic, acetic, propionic and butyric acid), the supernatants from liquid samples were filtered through a membrane filter with 0.2 μm pore size (13 mm; LABSOLUTE, Th. Geyer GmbH, Hamburg, Germany) and stored at $-20 \text{ }^\circ\text{C}$ or analyzed immediately. When needed, appropriate dilutions were prepared with deionized water and the samples were analyzed by using high performance liquid chromatography (HPLC; Shimadzu Scientific Instruments, US) equipped with a refractive index detector (RID) L-2490 and an ICsep column COREGEL87H3 (Transgenomic Inc., Omaha, NE, USA). The sample volume for HPLC measurement was 200 μL and the injection volume was 20 μL . The HPLC measurements were done with 5 mM H_2SO_4 as the eluent at a flow rate of 0.7 mL min^{-1} .

The pH value of the broth was measured in 200 μL liquid samples using a mini-pH meter (ISFET pH meter S2K922, ISFETCOM Co., Ltd., Hidaka, Japan) and the value was recorded after 90 s. For particular experiments with mediums B and C, the pH was determined as aforementioned after a centrifugation step at 20,817 $\times g$, 4 °C, 10 min.

2.7. Statistical Analysis

The CH_4 concentrations of the two stages were compared when the gas conversion and production was stable throughout several feeding cycles (variation was less than 10% in at least ten consecutive batch-cycle feedings) by means of analysis of variance (ANOVA). Tukey's post-hoc test was used for multiple comparisons with a confidence level of 0.05. RStudio [45], Graphpad (Graphpad Software, Inc., San Diego, CA, USA) or Microsoft Excel were used to compute the data. Microbial community

composition data were analyzed by principal coordinate analysis (PCoA) based on Bray–Curtis distances of relative abundance in addition to the absence and presence using the phyloseq package [41] version 1.30.0 in R [46] version 3.6.1. PCoA was plotted using the ggplot2 package [47] version 3.2.1.

3. Results and Discussion

3.1. Enrichment of the Hydrogenotrophic Community and Biomethanation Performance

During the first stage of the enrichment, CH₄ was formed within 24 h upon H₂/CO₂ feeding, and the process was stable for ~5 months. The rapid gas substrate conversion indicated high hydrogenotrophic methanogenesis activity in the inoculum. This observation is in agreement with a previous study [48]. However, the highest CH₄ concentration between feeding cycles was only ~90% (Figure S1). In the second stage of the enrichment, the CH₄ concentrations in six successive transfers (T1–T6) were as high as in the bioreactors working with sludge in the first stage (Table 1). The CH₄ concentration was 6% lower than the one described by Luo and Angelidaki [17], but was similar to that observed in another study [20].

Particle-free cultures were obtained after the third transfer and, therefore, the cell biomass from T3–T6 could be followed by spectrophotometry via optical density (OD₆₀₀) (Figure S2). On average, each transfer from T3 to T6 started with a biomass of 91 ± 22 mg L⁻¹, whereas the final biomass was, on average, 579 ± 26 mg L⁻¹. In terms of biomass and gas composition, no significant difference ($p \leq 0.05$) among transfers was found when comparing the end points of each transfer (Table 1). At the end of each culture transfer, the pH was ~8, a value similar to that reported by Kougiaris and colleagues [10]. Acetate was found in considerable concentrations from T1 to T5, but neither in the seed sludge (after ~5 months) nor in T6 (see Table 1), indicating that homoacetogenesis was a concomitant reaction alongside methanogenesis in our enriched hydrogenotrophic community. The variation in acetate concentrations among transfers could be associated with the cultivation time, especially for the particle-free enrichment cultures (T5 and T6), where the acetate concentration was generally low and the cultivation time was long.

The decrease in the acetate concentration at the end of the culture transfer (T6) suggests decreased homoacetogenic activity or increased acetate utilization via syntrophic acetate oxidation (SAO), since acetotrophic methanogens were absent in our enrichment cultures (see Section 3.2). Another explanation for the decrease could be acetate assimilation to build up microbial biomass, since hydrogenotrophic microbes can use an organic carbon source such as acetate when available. It has been reported that acetate is central to the carbon metabolism of autotrophic and heterotrophic microbes [49]. Despite the variations in acetate concentration, the observed values throughout the culture transfers were similar to those reported in other studies [10,19,24,26,30]. Since acetate was the main side product, the kinetics of acetate consumption were assessed in more detail during one batch cycle of feeding when the culture (T1) presented stable gas consumption in several consecutive batch cycles (Figure S3). Acetate was consumed during the first 7 h (4% consumption likely to build biomass) and then its concentration increased again (1% increase), although the final concentration was 3% less than the initial concentration. Propionate and butyrate were also detected and the highest concentrations were found in T1 and T3. However, their concentrations decreased over the consecutive transfers (Table 1). It is most likely that this effect was also related to the cultivation time of the culture transfers.

Table 1. Summary of process parameters during the enrichment in the first stage with sludge and in the second stage with six culture transfers (T1–T6).

Sample	Sludge ^b	T1 ^c	T2 ^c	T3 ^c	T4 ^c	T5 ^c	T6 ^c

Mean and standard deviation are shown. ^c Three biological replicates. Mean and standard deviation are shown. ^d Experimental conversion factor for biomass quantification: 1 OD₆₀₀ = 0.423 g L⁻¹ dry weight. Details are given in Figure S3.

3.2. Microbial Community Structure and Dynamics

Feeding the complex community with a rather simple substrate probably reduced the microbial diversity, as shown by Kougias and colleagues [10], but it could still maintain a number of cooperative as well as competing functional groups. The effect of H₂/CO₂ as selection factor shaping the bacterial and methanogenic communities resulted in a dynamic process throughout the enrichment, as visualized by PCoA (see the time trajectory in Figure 1). The first two axes explained 64% and 98% of the variance for the bacterial (Figure 1A) and methanogenic (Figure 1B) communities, respectively. Hence, a two-dimensional plot is sufficient to represent the relationship between the samples. Microbial communities were grouped according to transfers, which means that the communities of the same transfer were quite similar, but were different from those of the other transfers.

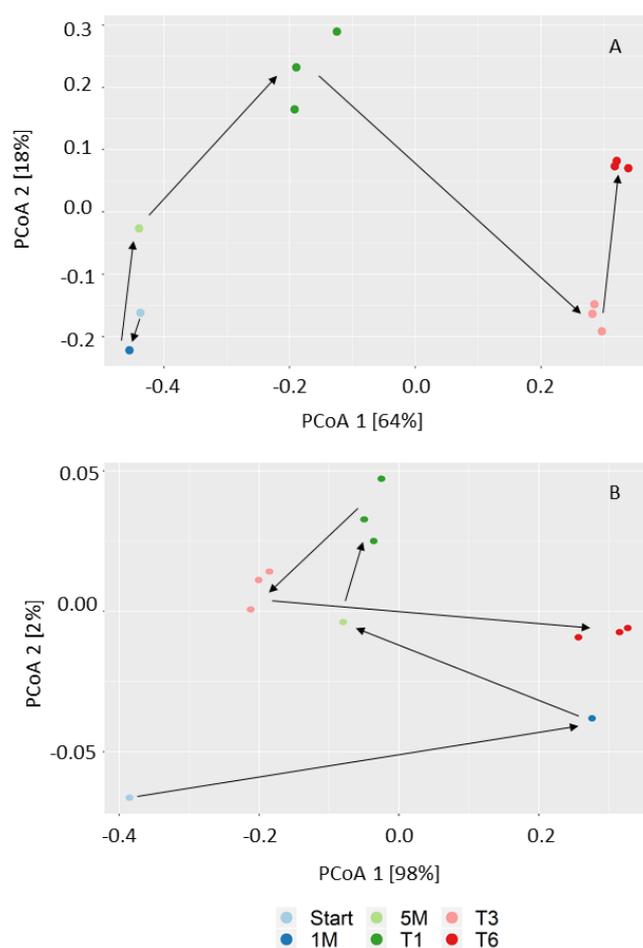

Figure 1. Principal coordinate analysis (PCoA) based on Bray–Curtis distances showing the microbial community shift during the enrichment. (A) Bacterial community (16S rRNA gene amplicon sequences) and (B) methanogenic community (*mcrA* gene amplicon sequences). The labels of the figure are as follows: inoculum (Start), one month (1 M), 5 months (5 M) after fed-batch feeding during the first stage; first transfer (T1), third transfer (T3), and sixth transfer (T6) after fed-batch feeding in the second stage.

As expected, based on the high ammonia level (5.84 g L⁻¹ NH₄-N) of the source digester, the methanogenic community in the inoculum was dominated by hydrogenotrophic methanogens affiliated to the genus *Methanobacterium* (Figure 2), which is in agreement with other studies on high ammonia level reactors [33–35]. Methanogens affiliated to the genus *Methanosarcina* were also present in the inoculum, but disappeared after one month of H₂/CO₂ feeding, despite their versatility in substrate utilization. It was proposed that H₂ feeding exerts a selection pressure that enriches hydrogenotrophic

methanogens [21,25], which could explain the disappearance of *Methanosarcina* and the complete dominance of strictly hydrogenotrophic methanogens in the enrichment. The H₂ uptake rate was reported to be one order of magnitude higher for the strict hydrogenotrophic methanogen *Methanococcus maripaludis* [50] than for the versatile methanogen *Methanosarcina barkeri* [51]; therefore, this aspect may also explain why *Methanosarcina* disappeared despite the fact that it can grow on H₂/CO₂.

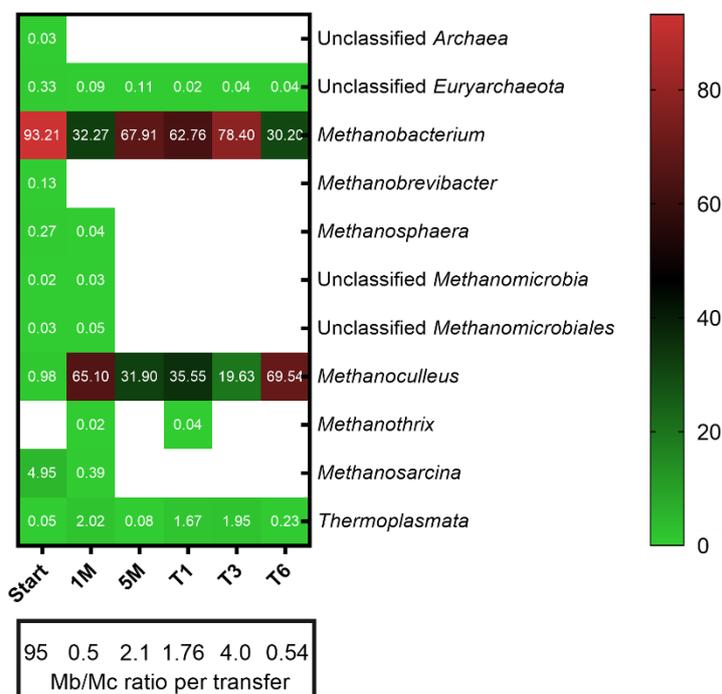

Figure 2. Methanogenic community structure in different stages of the enrichment. Taxa with a relative abundance less than 0.01% were filtered out from all samples. Numbers represent the relative abundance in percent and blank space indicates the absence of the respective taxa. The ratio of the most dominant methanogens, *Methanobacterium* (Mb) and *Methanoculleus* (Mc), among transfers is shown. Mean values of three biological replicates are presented for T1, T3 and T6 whereas single values are shown for Start, 1 M and 5 M.

The species of the genus *Methanoculleus* dominated (65% of the total methanogenic community) after one month of fed-batch feeding of H₂/CO₂, but decreased to 32% after 5 months during the first stage of the enrichment. In the second stage, *Methanobacterium* dominated the methanogenic community in the inoculum (5M), but after H₂/CO₂ fed-batch feeding, *Methanoculleus* increased in relative abundance and eventually became the dominant methanogen (T6). Other studies reported *Methanoculleus* [25] and *Methanobacteriales* to be the dominant methanogenic taxa [17], regardless of the reactor configuration. Members of the order *Methanomassiliicoccales* (class *Thermoplasmata* Figure 2) were present until the end of the experiment, with low relative abundance, as reported in another ex situ biomethanation study [26].

In reactors operated under thermophilic conditions (≥ 55 °C), *Methanothermobacter* and *Methanoculleus* dominated the methanogenic community [10,24,25,52]. Consequently, we suggest that, regardless of the operational temperature, methanogens affiliated to *Methanomicrobiaceae* and *Methanobacteriaceae* seem to be key players of ex situ biomethanation processes, since both families dominated the methanogenic community of our enrichment culture.

The bacterial community (Figure 3) was an integral part of the microbial community because VFA were produced and consumed (Table 1). Acetate formation and consumption were mainly observed, which indicates homoacetogenesis and SAO. At the end of the enrichment (T6), the dominant phylum was *Firmicutes* (91%) (Figure S4), which is consistent with previous findings [21], followed by

the phylum *Bacteroidetes* (9%). Cooperation and competition can be expected in H₂ biomethanation systems, since the microbial community can be composed of hydrogenotrophic and acetotrophic methanogens, homoacetogenic bacteria, and syntrophic acetate-oxidizing bacteria (SAOB) [10,25], as well as chain-elongating, predatory and scavenger microorganisms. In the present study, acetotrophic methanogens were not present due to the mainly hydrogenotrophic seed sludge. In general, it is conceivable that strict acetotrophic methanogens (*Methanotherix*) coexist with homoacetogens in hydrogenotrophic communities. While a lower abundance of *Firmicutes* was reported in earlier studies [10,23], a similar abundance as in this study was found by other studies [25,52,53]. In contrast, *Bacteroidetes* was found to be the dominant phylum by another study [54].

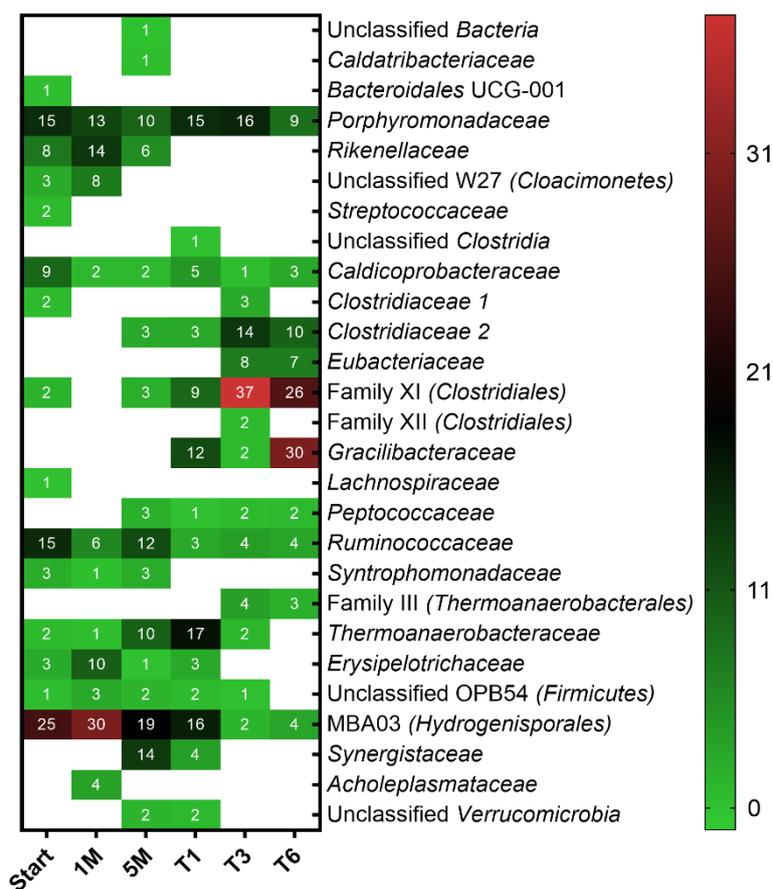

Figure 3. Bacterial community structure in different stages of the enrichment. Taxa with relative abundances less than 1% were filtered out from all samples. Numbers represent the relative abundance in percent and blank spaces indicate the absence of the respective taxa. Mean values of three biological replicates are presented for T1, T3 and T6 whereas single values are shown for Start, 1 M and 5 M.

Throughout the enrichment, the abundance of the class *Clostridia* increased to 86% in the sixth transfer (Figure S5), whereas the classes *Bacteroidia* and OPB54 (*Firmicutes*), which were dominant in the inoculum, decreased in relative abundance to 9% and 5%, respectively (Figure S5). The production of acetate from H₂/CO₂ (Table 1) indicated homoacetogenesis, which can be attributed to members of the *Clostridiales* that dominated the bacterial community throughout the enrichment (Figure S6). Some members of this order are crucial for homoacetogenesis [55] or SAO [56]. Homoacetogens and SAOB use the Wood–Ljungdahl pathway in the reductive or oxidative direction to produce acetate from CO₂ or to oxidize acetate to CO₂, respectively [55,57,58].

Mesophilic acetogens belong predominantly to the orders *Clostridiales* and *Selenomonadales*, whereas thermophilic acetogens belong to the order *Thermoanaerobacterales* [59]. *Clostridiales* and

Thermoanaerobacterales were both present in the enrichment culture (Figure S6) and, together with the detection of acetate (Table 1), indicate the presence of acetogenic bacteria.

It is notable that, in T6, *Lutispora* was the predominant genus, with a relative abundance of 31% (Figure S7). The only described species of this genus is a thermophile not known to be a homoacetogen, which suggests that novel homoacetogenic species may be present in the enrichment culture and supports the need to further explore such unknown microbiota. This genus belongs to the clostridial family *Gracilibacteraceae*, which was found to be in low relative abundance in a former study [26]. Other genera such as MBA03 (*Hydrogenisporales*) (19%), unclassified Family XI (*Clostridiales*) (15%), *Natronincola* (10%), unclassified *Rikenellaceae* (11%), *Fastidiosipila* (8%), *Garciella* (7%), and *Petrimonas* (5%) were also abundant in the bacterial community (Figure S7).

The acetate consumption could have occurred via SAO (e.g., by members of the classes *Synergistia* or OPB54 (*Firmicutes*) [60]), or could have been assimilated by acetogens and hydrogenotrophic methanogens to build biomass. The order *Thermoanaerobacterales* (class *Clostridia*) was present in lower abundance (3% in T6), with its dynamic behavior in the second stage reaching similar levels as in the inoculum. Within this order, bacteria affiliated to the genus *Gelria* (family *Thermoanaerobacteraceae*) were found. This family comprises two species known as SAOB (*Thermacetogenium phaeum* and *Tepidanaerobacter acetatoxydans*), and *Gelria* was also suggested to be involved in SAO [61]. Although the relative abundance of this genus decreased drastically towards T6, a syntrophic association with the two most dominant methanogens (*Methanoculleus* and *Methanobacterium*) of the enrichment culture is conceivable. Hence, the low concentration of acetate, especially in T6 (~123 mg L⁻¹) could be explained by the activity of SAOB or high acetate assimilation by the microbial community. The SAO function of the enrichment culture might be a shared task carried out by different phylotypes, since the biggest difference in the abundance of *Gelria* and *Tepidanaerobacter* genera was observed at the end of T1. *Tepidanaerobacter syntrophicus* was found in an ex situ biomethanation setup and it was suggested that this species was responsible for SAO [21]. Further investigations are needed by combining different omics approaches with improved isolation attempts in order to explore the largely unknown function of microorganisms represented only by sequence data.

3.3. Microbial Resource Management for Selective Production of Methane

3.3.1. Effect of Medium Composition

Our ex situ biomethanation experiment concomitantly enriched homoacetogenic bacteria and hydrogenotrophic methanogens in a similar manner to other studies [10,19,24,30]. It was argued that operational conditions are crucial to shaping a microbial community composition that, ultimately, will lead to a maximized CH₄ yield [26]. The control of such parameters falls into the concept of microbial resource management for the selective production of any desired target molecule [12,62]. Here, we showed that selective CH₄ production with enrichment cultures that contain both homoacetogenic bacteria and hydrogenotrophic methanogens is possible via controlling the medium composition. We explored the effect of several medium components on the products of the hydrogenotrophic enrichment culture in a separate set of experiments, with a focus on the products (CH₄ and VFA) and not the microbial community. The inocula for these experiments were derived from the last culture transfer of the enrichment phase (T11).

First, we assessed the effect of yeast extract in a medium containing cysteine-HCl as a reducing agent by comparing its cultivation in mineral medium with (medium A) or without yeast extract (medium B). Acetate was produced up to ~5 mM in both media, whereas formate was not produced at all (Figure 4A). However, medium A yielded 25% more biomass than medium B after the first batch-cycle feeding ($p = 0.0031$), even though the yeast extract concentration was as low as 0.25 mg L⁻¹ (Figure 4B). A cultivation broth with such low concentrations of yeast extract is considered a mineral medium [63].

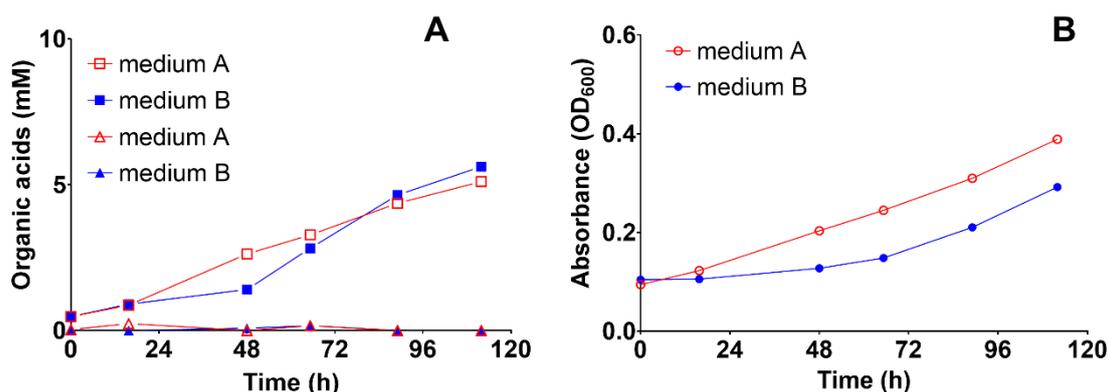

Figure 4. The effect of yeast extract on the production of acetic and formic acid and biomass during autotrophic feeding with H_2/CO_2 (80:20) in a 1-L bioreactors with medium A (containing 0.2 g L^{-1} yeast extract) and medium B (free of yeast extract but containing vitamins). Both media were reduced with cysteine-HCl. (A) Acetic acid and formic acid concentration profiles during the first batch cycle, and (B) microbial biomass growth, as measured by optical density at 600 nm during the first batch cycle. The experiments were conducted in two biological replicates with orbital shaking at 200 rpm. Each data point depicts the median and the range (invisible error bars are smaller than the symbol). Square: acetic acid, triangle: formic acid, circle: biomass.

In a second experiment, we tested the effect of the reducing agent on VFA formation in medium B (containing cysteine-HCl as reducing agent) and medium C (containing sodium sulfide as reducing agent). Acetate accumulated in both cultures with mediums B and C, but after ~ 300 h the concentration started to decrease and, concomitantly, formate concentration started to increase (Figure 5). This observation could indicate that formate formation occurred as a result of acetate degradation, meaning that it could be related to SAO (involving interspecies formate transfer). However, the possibility of direct formate production from H_2/CO_2 cannot be ruled out. The acetate concentration in medium B was as high as 20 mM (Figure 5A), whereas incubation for ~ 500 h in medium C yielded no acetate (Figure 5B). If cysteine-HCl is taken into account as an additional carbon source, up to 3.42 mM acetate is expected, which is far less than the accumulated acetate concentration in medium B (Figure 5A), suggesting that acetate was mainly produced from H_2/CO_2 . The final formate concentrations after 500 h were 2.4 and 2.9 mM in the cultures with mediums B and C, respectively (Figure 5). After 500 h of operation, when the batch-cycle feeding was stopped, formate was rapidly consumed (data not shown). To our knowledge, experimental evidence of formate production in ex situ biomethanation has not been reported hitherto. Formate is an alternative electron donor for hydrogenotrophic methanogens [64] and a former study showed formate synthesis from H_2/CO_2 by bacteria [65]. Furthermore, pure cultures of hydrogenotrophic methanogens (*Methanobacterium formicicum*) or acetogenic bacteria transiently produced formate during H_2/CO_2 metabolism [66,67]. Hence, it can be inferred that homoacetogens, SAOB and hydrogenotrophic methanogens could have contributed to concomitant formate formation, along with methanogenesis. The observed formate concentration could be the result of dynamic production and consumption. The measurement of formate in micromolar concentrations is rather difficult [64]. This might explain why formate has not been reported in liquid products in other studies on ex situ biomethanation. Altogether, the results confirmed that formate was an intermediate during ex situ biomethanation; however, its exact mechanisms are still unclear. Reducing the sampling time intervals was important to allow formate determination in the broth. Biomass growth increased until the end of the experiment with medium B, whereas a plateau was reached after ~ 375 h with medium C (biomass concentration in medium B was 24% higher than in medium C). This may be explained by sulfur depletion after prolonged incubation in medium C because the medium was not replenished during the experimental period (the sulfur concentrations in medium B and C were 0.374 and 0.208 mM, respectively). The depletion of trace elements, which causes process imbalances because they are

essential in enzyme complexes [68], may also explain the decreased CH_4 production in both media after prolonged incubation. Although the biomass was less in medium C, the CH_4 concentration was higher than in medium B (32.5%). Additionally, the pH drop after 500 h of fed-batch operation was not significantly different ($p < 0.05$) between the two media, as it decreased from 9.08 ± 0.05 and 9.03 ± 0.05 to 7.54 ± 0.18 and 7.73 ± 0.04 for medium B and C, respectively.

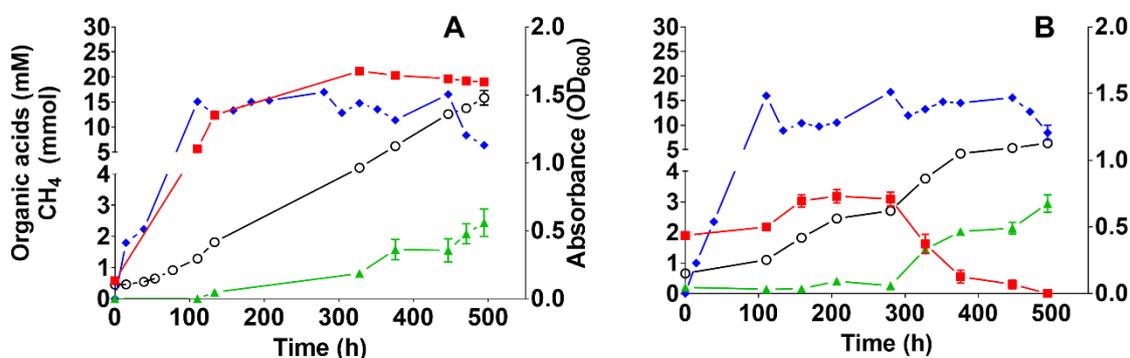

Figure 5. Effect of the reducing agent on the anaerobic conversion of H_2/CO_2 (80:20; fed-batch) in 1-L bioreactors following shaking at 200 rpm. (A) Medium B (mineral medium free of yeast extract, supplemented with vitamins and reduced with cysteine-HCl), and (B) medium C (prepared as medium B but containing sodium sulfide instead of cysteine-HCl as reducing agent; see Section 2.2). The experiments were conducted with two biological replicates and each data point depicts the median and range. Red square: acetic acid (mM), green triangle: formic acid (mM), blue diamond: CH_4 (mmol), and black open circle: biomass.

3.3.2. Effect of Stirring Intensity

Next, the effect of the stirring intensity on the CH_4 formation rate was analyzed. Improved mixing was reported to enhance the gas mass transfer and, hence, the CH_4 formation rate [3,17]. As shown in Figure 6, the CH_4 formation rate increased proportionally, with the stirring intensity up to a maximum of $\sim 9 \text{ mmol L}^{-1} \text{ h}^{-1}$ at 750 rpm. However, in this particle-free enrichment culture growing in a mineral medium, increasing the stirring intensity further to ≥ 1000 rpm was detrimental (Figure 6) for both CH_4 formation and H_2 consumption rates. Although shaking exerts a different type of mixing than stirring does, our results are in line with a previous study, where shaking intensities of 200–250 rpm were already detrimental for biomethanation performed with sludge [28]. On the contrary, an in situ biomethanation study working with sludge reported improved gas mass transfer with a stirring intensity as high as 1000 rpm [69]. This indicates that sludge can better resist shear forces caused by high stirring intensity than enrichment cultures, so that selecting a proper mixing intensity is dependent on the type of liquid matrix used as the biocatalyst. Under optimal conditions, the enrichment culture was capable of consuming the gaseous substrate within 24 h or less, similar to times reported elsewhere [17,70]. It is important to note that high shear (stirring speed ≥ 1000 rpm) may have a negative effect on the syntrophic interactions between bacteria and methanogens.

With an optimized medium composition (medium C) and mixing intensity (750 rpm), we obtained $\geq 97\%$ CH_4 in the gas phase, which is comparable to other studies [1,6]. Although other measures may also affect the process performance, microbial resource management for biomethanation seems to be important when enriched mixed cultures are used as biocatalysts.

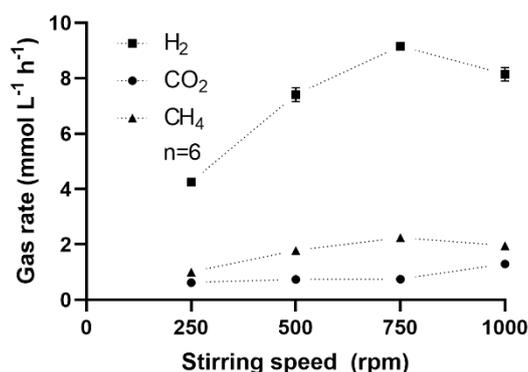

Figure 6. Effect of the stirring intensity on the consumption and formation rate of gases in a 1-L bioreactor with medium C. Bottles were pressurized at ~2.2 bar with a gas mixture of H₂ (80%) and CO₂ (20%). The rate for each stirring speed was repeated three times in duplicate biological bioreactors. Mean and standard deviation ($n = 6$) are shown (invisible error bars are smaller than the symbol).

4. Conclusions

We showed the enrichment of a hydrogenotrophic community that successfully produced grid quality CH₄ ($\geq 97\%$) through ex situ biomethanation. The methanogenic community was dominated by *Methanoculleus* and *Methanobacterium*. Microbial resource management allowed for the control of homoacetogenesis by directing the carbon and electron flows towards selective CH₄ production by carefully defining the medium composition. The reducing agent played a pivotal role in controlling the production of acetate, while stirring intensities that were too high negatively affected ex situ biomethanation in a highly enriched particle-free community. Several bacterial taxa could be responsible for homoacetogenesis (mainly *Clostridia*). Thus, further investigations are needed to elucidate the physiological role of the most abundant bacterial genera in the hydrogenotrophic community.
