Introduction

Nonadiabatic transition occurs most efficiently when the reactive flux is prepared in the proximity of the conical intersection (CI) seam. ^{1,2} In the S-CH₃ bond predissociation reaction of thioanisole (C₆H₅SCH₃), the reactive flux prepared by the excitation to the first electronically excited (S₁; ππ*) state bifurcates into either the adiabatic or nonadiabatic pathway at the first S₁/S₂ conical intersection where the upper-lying S₂ (πσ*) state is repulsive along the S-CH₃ bond elongation coordinate. ³⁻⁵ The flux sliding on S₂ then undergoes another bifurcation at the second S₀/S₂ conical intersection to give either the excited (Ã) or ground (X̃) state of the C₆H₅S• radical at the asymptotic limit as the former or latter is diabatically correlated from S₀ or S₂, respectively, Fig. 1. The nonadiabatic transition efficiency is then reflected in the X̃/Ã product branching ratio, giving the quantitative estimation of the otherwise unambiguous nonadiabatic transition probability. Both S₁/S₂ and S₀/S₂ conical intersections are located at the planar geometry and share the same branching plane in terms of its gradient and coupling vectors. ³⁻⁵ Furthermore, as the S₁/S₂ conical intersection is correlated to the S₀/S₂ conical intersection by the repulsive S₂ state in the very short S-CH₃ bond length region, the quantum mechanical character of the initial reactive flux especially along the degrees of freedom orthogonal to the reaction coordinate is

Multidimensional characterization of the conical intersection seam in the normal mode space†

Heesung Lee,[‡] So-Yeon Kim[‡] and Sang Kyu Kim^{†*}

Multidimensional conical intersection seam has been characterized by utilizing the dynamic resonances in the nonadiabatic transition probability experimentally observed in the predissociation of thioanisole isotopomers. The nonadiabatic bifurcation behavior of the reactive flux into either the Herzberg type-I (electronic) or type-II (vibrational) predissociation pathway is found to be strongly dependent on the quantum nature of the S₁/S₂ vibronic eigenstate, providing the essential information about structure and dynamic character of the conical intersection seam projected onto the normal mode space. By modifying the nature of the normal mode space through partial or full H/D substitution of the molecule, multiple aspects of the conical intersection seam could be characterized from different viewpoints set by the adjusted normal mode space. Theoretical calculations of potential energy curves along selected normal mode displacements support the experiment.

not likely to be modified. ³⁻⁸ This has provided a great chance to characterize the S₁/S₂ conical intersection seam by monitoring the X̃/Ã product branching ratio with varying the S₁ vibronic mode excitation within the Franck-Condon region.

A decade ago, our group reported the experimental result that the X̃/Ã branching ratio (*I*) shows a striking dynamic resonance upon a specific vibronic mode excitation of thioanisole. ³ This has provided the unique opportunity to unravel the structure and dynamic property of the conical intersection, as the resonance-like peak in the nonadiabatic transition probability should represent that the reactive flux prepared by

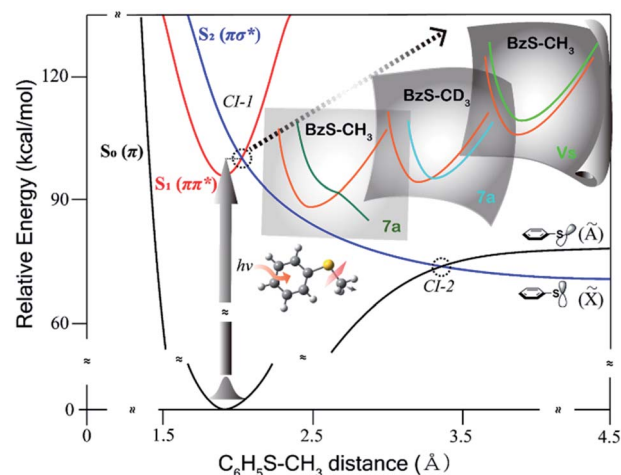

Fig. 1 Schematic potential energy curves along the S-CH₃ bond elongation coordinate. Projections of the conical intersection seam onto the different normal mode spaces are depicted just as approximated cartoons.

the specific vibronic mode excitation resides in the proximity of the conical intersection. The vibronic mode responsible for the dynamic resonance, from the spectroscopic analysis and theoretical calculation, has been identified to be the 7a mode which involves the S-CH₃ asymmetric stretching.^{3–13} This mode should be at least partially parallel to the gradient vector comprising the branching plane of the S₁/S₂ conical intersection. The flux prepared by the 7a mode excitation is thus expected to undergo the nonadiabatic transition quite efficiently. Recently, our group has carried out the picosecond time-resolved pump-probe experiment to unravel the temporal behavior of the reactive flux associated with each of many different S₁ vibronic modes of thioanisole.⁵ Interestingly, it has been found that the reactive flux at the 7a mode excitation bifurcates into the adiabatic or nonadiabatic pathway with quite distinct reaction rates. In the adiabatic channel, the nuclear motion of the reactive flux follows the low-lying adiabatic surface under the S₁/S₂ conical intersection and the S₁ vibrational energy is fully or partially utilized to overcome the multi-dimensional adiabatic reaction barrier. This belongs to the Herzberg type-II vibrational predissociation.^{14,15} The adiabatic nature of the flux then persists along the entire reaction pathway, avoiding the curve crossing at the S₀/S₂ conical intersection to give the \dot{A} state of the C₆H₅S^{*} radical rather exclusively at the asymptotic limit. On the other hand, in the nonadiabatic channel, the reactive flux on the upper adiabatic surface above the S₁/S₂ conical intersection undergoes the nonadiabatic transition into the low-lying adiabatic surface most efficiently through the conical intersection, and this should belong to the Herzberg type-I electronic predissociation.^{14,15} The resultant flux then bifurcates again at the S₀/S₂ conical intersection this time with the significant probability of the nonadiabatic transition, as the reactive flux which was nonadiabatically leaked from the first S₁/S₂ conical intersection should have been quantum-mechanically shaped for the efficient nonadiabatic passage through the second S₀/S₂ conical intersection. The reaction rate on the adiabatic passage (Herzberg type-II) has been found to be much slower than that of the nonadiabatic path (Herzberg type-I). The experimental fact that the nonadiabatic transition probability strongly depends on the initial quantum state of the reactive flux indicates that the structure and energetics of the conical intersection seam could be possibly characterized in the normal mode space over the Franck–Condon region.

In contrast to the fact that the nonadiabatic transition probability is enhanced by the excitation of the 7a mode only for the bare thioanisole, it has been found that the three more vibronic modes in addition to 7a are responsible for dynamic resonances in the partially deuterated thioanisole (C₆H₅S-CD₃).⁶ These modes include ν_s (S-CD₃ symmetric stretching), β (CD₃ bending), and an unidentified mixed mode. The dynamic resonances at multiple vibronic modes already reflect that the conical intersection is located on the multi-dimensional seam. Moreover, this suggests that the gradient vector comprising the branching plane may be described by the combination of normal modes in terms of their structural changes and associated energetics. What would be the reason why C₆H₅S-CD₃ shows multiple dynamic resonances whereas

the only 7a mode is responsible for a dynamic resonance in the undeuterated thioanisole (C₆H₅S-CH₃)? As the electronic structures are expected to be little influenced by the H/D substitution, it is most likely that the structure and electronic property of the S₁/S₂ conical intersection seam would be identical for both isotopomers. The subtle differences in the nuclear displacement vectors of the normal modes of C₆H₅S-CH₃ and C₆H₅S-CD₃ should be then responsible for the different behaviors of dynamic resonances in these two isotopomers. In other words, the conical intersection seam associated with the sulfur–methyl bond dissociation has been projected onto different sets of normal mode coordinates for different isotopomers. In this sense, one may then be able to characterize the conical intersection seam in a number of different normal mode spaces subject to subtle changes by the partial or full H/D substitution of the molecule. As a matter of fact, our group reported that dynamic resonances at the 7a or ν_s mode excitation are quite robust for the particular thioanisoles of which the methyl moiety was partially deuterated (C₆H₅S-CH₂D, C₆H₅S-CHD₂).^{7,9} In this work, for the more complete characterization of the conical intersection, we have carried out the experiment on the fully deuterated thioanisole (C₆D₅S-CD₃) as well as the partially deuterated in total but fully deuterated one on the benzene moiety (C₆D₅S-CH₃). More importantly, we have carried out theoretical calculations on the first (S₁) and second (S₂) excited potential energy curves with respect to 7a and ν_s normal modes, unravelling the nature of the conical intersection seen from many different viewpoints set by different normal mode spaces of various isotopomers.

Methods

The sample (C₆D₅S-CH₃; 98.5% and C₆D₅S-CD₃; 97.17%) was purchased (MediGen Co.) and used without further purification. The gas mixture of the sample with He (Ne, Ar) was supersonically expanded through a nozzle orifice and skimmed into the differentially-pumped vacuum chamber with the backing pressure of 1–2 atmosphere at the repetition rate of 10 Hz. Detailed experimental setup had been described in previous works.^{7,9,16} The UV laser pulse (275–288 nm, 5 ns duration) was prepared by the frequency doubling of the visible output of the dye laser (Scanmate II, Lambda Physik) pumped by the second harmonic (532 nm) of a Nd:YAG laser (Powerlite 8010) through a beta barium borate (BBO) crystal. For velocity map imaging (VMI)^{17,18} experiment, the aforementioned first laser pulse (pump) was used to excite the molecule whereas the second UV laser pulse (probe) was employed to ionize the nascent methyl radical *via* its 3P₂²A'' ($\nu = 0$) \leftarrow \tilde{X}^2 A'' transition of $\dot{C}H_3$ (333.484 nm) or $\dot{C}D_3$ (333.826 nm). The delay time between pump and probe laser pulses was fixed at 25 ns. The polarization of the pump laser pulse was parallel to a detector plate in the VMI experiment. For the two-color slow-electron velocity map imaging (SEVI)^{19,20} experiment, the probe (ionization) pulse was delayed by 5 ns with respect to the pump laser pulse. The position-sensitive detector equipped with the dual microchannel plates (MCP; Burle, $\phi = 40$ mm) and phosphor screen was used for both VMI and SEVI experiments. A CCD

camera (IDS USB 2.0 UI-2230SE-M-GL) was employed to capture the images using the LABVIEW based acquisition program.²¹ Raw images were reconstructed by the MEVELER program.²² The wavelength was calibrated by the Wavemaster (Continuum). The VMI and SEVI experimental results were calibrated according to the well-known energetics of O₂ dissociation dynamics.

Results and discussion

Resonance-enhanced two-photon ionization (R2PI) spectra of C₆D₅S-CD₃ and C₆D₅S-CH₃ show very-well resolved S₁-S₀ vibronic structures, Fig. 2. Mode assignments are quite straightforward as those of similar thioanisoles had been already spectroscopically established in earlier studies^{3,6,7} and also confirmed by SEVI spectroscopies in this work (see the ESI†). Photofragment-excitation (PHOFEX) spectrum taken by probing the nascent CD₃ or CH₃ fragment from C₆D₅S-CD₃ or C₆D₅S-CH₃ as a function of the S₁-S₀ excitation energy, respectively, is also shown, Fig. 2. While R2PI and PHOFEX spectra of both isotopomers are almost identical in all the energy region explored here, it is quite surprising to observe that the 7a vibronic band of C₆D₅S-CH₃ is nearly absent in R2PI

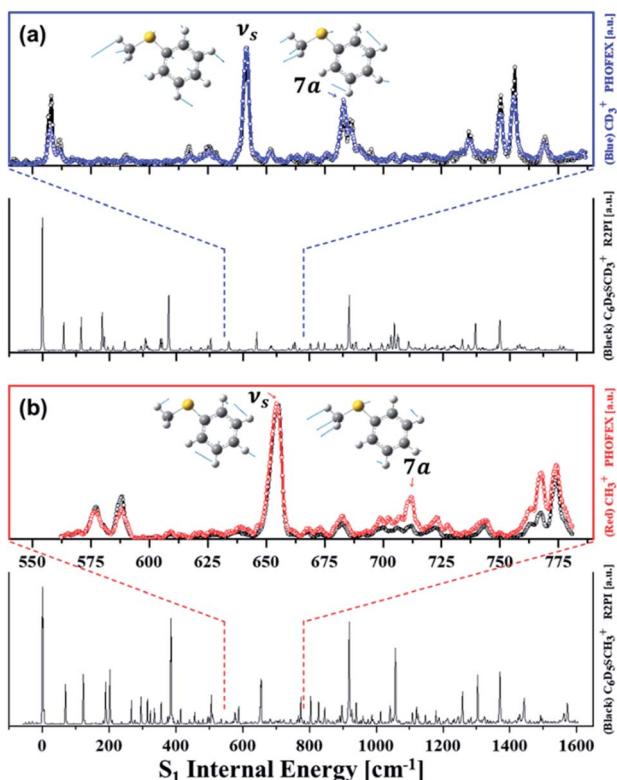

Fig. 2 (a) (black) R2PI or (blue) (1 + 1') PHOFEX spectrum of C₆D₅S-CD₃ (b) (black) R2PI or (red) (1 + 1') PHOFEX spectrum of C₆D₅S-CH₃; *v_s*: symmetric S-CH₃ (or S-CD₃) stretching mode, 7a: anti-symmetric S-CH₃ (or S-CD₃) stretching mode.^{3,6,7,23} Inset images depict S₁ normal mode displacement vectors calculated by the Gaussian 09 software²⁴ using the B3LYP method with the 6-311++G(3df, 3pd) basis set. Detailed mode assignments are summarized in Table S2.†

The sudden shifts of the translational energy distributions are noticeable at dynamic resonances.

whereas the significant PHOFEX signal is observed at the same mode. We have found that the 7a mode of C₆D₅S-CH₃ shows the strongly enhanced \tilde{X}/\tilde{A} product branching ratio, indicating that the nonadiabatic transition is highly facilitated by the 7a mode excitation (*vide infra*). The experimental fact that the 7a mode is inactive in the R2PI spectrum, therefore, strongly suggests that the corresponding lifetime may be quite shortened. Translational energy distributions obtained by the velocity-map ion images taken from the ionization of nascent CD₃ or CH₃ fragment from C₆D₅S-CD₃ and C₆D₅S-CH₃ are shown in Fig. 3, respectively. In most of bands, the \tilde{X}/\tilde{A} product branching ratio remains low, indicating that the predissociation reaction is pretty much adiabatic in nature. On the other hand, it is obvious that the \tilde{X}/\tilde{A} product branching ratio shows resonances at both 7a and *v_s* modes for C₆D₅S-CD₃, whereas it stands out only for the 7a mode for C₆D₅S-CH₃. The \tilde{X}/\tilde{A} product branching ratio (*I*) for C₆D₅S-CD₃ is estimated to be 0.22 ± 0.06 or 0.34 ± 0.05 for the *v_s* or 7a mode, respectively, compared to the value of 0.04 ± 0.03 for the zero-point energy level. This indicates that both *v_s* and 7a mode excitations are effective in facilitating the nonadiabatic channel in the S-CD₃ predissociation process while the latter seems to be more efficient. On the other hand, the \tilde{X}/\tilde{A} product branching ratio is measured to be 0.19 ± 0.02 or 0.43 ± 0.03 at *v_s* or 7a mode of C₆D₅S-CH₃, respectively, compared to *I* ~ 0.08 ± 0.04 at its S₁ zero-point level. This experimental finding suggests that the 7a mode excitation of C₆D₅S-CH₃ is much more efficient in expediting the nonadiabatic path compared to *v_s*, Table 1. The main question is then how these data could be interpreted qualitatively or more ideally quantitatively. As the \tilde{X}/\tilde{A} product branching ratio is the consequence from the competition between the nonadiabatic

^a Ref. 3. ^b Ref. 6. ^c This work [cm^{-1}].

electronic predissociation (Herzberg type-I) and adiabatic vibrational predissociation (Herzberg type-II), it may reflect the extent of the proximity of the corresponding quantum state to the conical intersection seam in terms of energetics and structures. In other words, the larger \tilde{X}/\tilde{A} product branching ratio results from the higher probability of the nonadiabatic electronic predissociation process, and this may be ascribed to that the associated quantum level is closer to the conical intersection seam by any means. In this sense, the experimentally measured \tilde{X}/\tilde{A} branching ratios in all different isotopomers represent the projections of the S_1/S_2 conical intersection seam onto different normal mode platforms.

Obviously, it is nontrivial to depict a multidimensional map of the conical intersection seam from the present experimental results alone although the proximity of the quantum level to the conical intersection seam is certainly correlated with the measured \tilde{X}/\tilde{A} product branching ratio. Instead of trying to describe the conical intersection seam directly, we have carried out theoretical calculations of potential energy surfaces for various isotopomers particularly along the critical modes of ν_s or 7a, Fig. 4. First of all, it is very interesting to find out that the S_1/S_2 potential energy surfaces along the ν_s or 7a normal mode are so different for different isotopomers. Namely, the energetics and gradients associated with curve crossing are strongly influenced by the subtle difference of the normal mode space induced by the combinatorial way of the H/D substitution. It is remarkable that the S_1/S_2 curve crossing points calculated along the one-dimensional coordinate are extremely valuable for the interpretation of the experiment as below. It should be noted that the \tilde{X}/\tilde{A} product branching ratios should linearly correlate with the bifurcation ratios of the reactive fluxes prepared near the conical intersection. Therefore, the qualitative comparison of the \tilde{X}/\tilde{A} product branching ratios among various isotopomers based on differences in the S_1/S_2 potential energy surface crossings should be still reasonable. For comparison of the experiment with theoretical calculation, we will discuss the results of all four thioanisole isotopomers ($C_6H_5S-CH_3$, $C_6D_5S-CH_3$, $C_6H_5S-CD_3$, and $C_6D_5S-CD_3$).

The most dramatic shape of the conical intersection, for example, could be inferred from the calculated S_1/S_2 curve crossing along the 7a mode of $C_6H_5S-CH_3$ or $C_6D_5S-CH_3$, giving the \tilde{X}/\tilde{A} product branching ratio of 0.416 ± 0.033³ or 0.43 ± 0.03, respectively (Fig. 4(a) and (c)). In these circumstances, the S_1/S_2 curve crossing produces the low-lying repulsive adiabatic curve along the 7a mode extension. This would certainly facilitate the rather fast escape of the reactive flux trapped in the upper adiabatic curve onto the repulsive part of the potential energy

curve leading to the predissociation reaction. The exceptionally high \tilde{X}/\tilde{A} product branching ratio at 7a for both $C_6H_5S-CH_3$ and $C_6D_5S-CH_3$ indicates that the corresponding reactive flux undergoes the nonadiabatic transition with the significantly high probability. It should be reminded that the nonadiabatic reaction path does not give the \tilde{X} product exclusively at the asymptotic limit. Rather, it gives rise to both \tilde{A} and \tilde{X} products with the former of the relatively even higher probability in most cases.⁵ In this regard, the probability of bifurcation into the

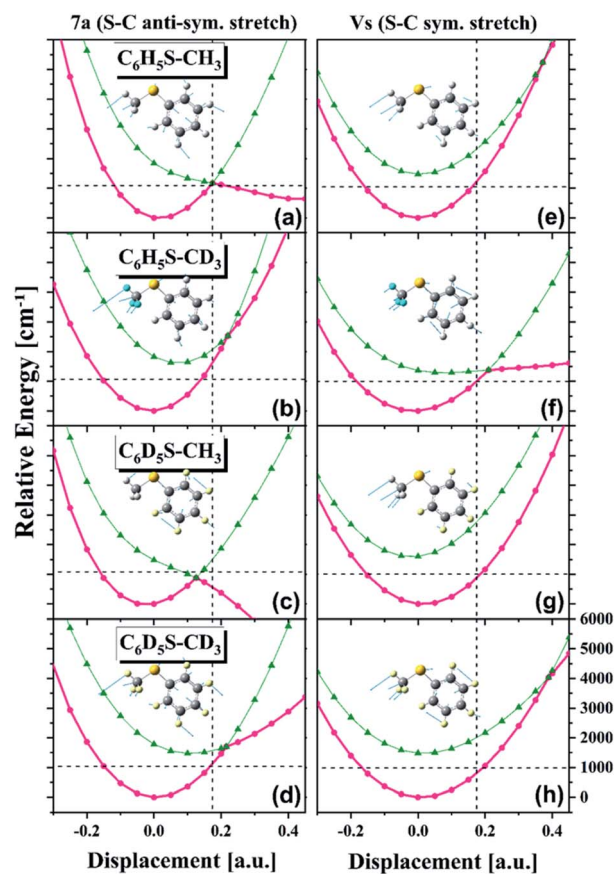

Fig. 4 Calculated potential energy curves along (left) 7a and (right) ν_s normal modes for four thioanisole isotopomers. Pink and olive lines are supposed to represent adiabatic S_1 and S_2 states, respectively. Relative electronic energies (ordinate) are plotted versus the nuclear displacement associated with specific normal modes (abscissa). Excited states have been calculated using the TDDFT method with the 6-311++G (3df, 3pd) basis set. Positions in terms of the energy and nuclear displacement of the S_1/S_2 curve crossing predicted in the bare thioanisole along the 7a mode are drawn as dotted lines for the comparison.

nonadiabatic channel at the $7a$ mode excitation of $C_6H_5S-CH_3$ or $C_6D_5S-CH_3$, relative to the adiabatic channel, should be regarded to be much higher than implied by the experimentally measured \tilde{X}/\tilde{A} product branching ratio, although time-resolved dynamic studies are necessary for the more quantitative argument. The repulsive nature of the S_2 diabatic curve along the $7a$ mode particularly stands out for $C_6D_5S-CH_3$, Fig. 4(c). This may explain the peculiar spectral features observed in R2PI and PHOFEX spectra of $C_6D_5S-CH_3$ (*vide supra*) in Fig. 2. The experimental finding that the R2PI signal is almost absent at the $7a$ mode excitation implies that the corresponding lifetime may be exceptionally short as the R2PI signal gets significant strength only when the S_1 state survives long enough during the laser ionization process by the nanosecond laser pulse. Overall, the S_1/S_2 crossing point along the $7a$ mode is found to be located around 1200 cm^{-1} above the S_1 minimum energy point for $C_6H_5S-CH_3$ and $C_6D_5S-CH_3$, Fig. 4(a) and (c). Considering the zero-point energy of $\sim 360\text{ cm}^{-1}$ for the $7a$ mode, this energetic position of the curve crossing point is quite close to the first quanta of the $7a$ mode, suggesting that the conical intersection is likely to be easily accessed by the $7a$ mode excitation of those molecules. For all other isotopomers, the S_1/S_2 curve crossing points along the $7a$ mode are predicted to be located at $\sim 2000\text{ cm}^{-1}$ or less above the S_1 minimum energy points, Fig. 4(a)–(d). These energetic positions are still close to the first quanta of the $7a$ mode considering that the calculated are often overestimated. The significantly large \tilde{X}/\tilde{A} product branching ratio of 0.38 ± 0.04 or 0.34 ± 0.05 estimated for the $7a$ mode excitation of $C_6H_5S-CD_3$ or $C_6D_5S-CD_3$, respectively, reflects that the corresponding vibronic excitation prepares the reactive flux at the conical intersection seam along which the $S-CD_3$ bond elongation should be effectively coupled. At the present time, it is less straightforward to quantify the structural and energetic characteristics from the comparison of the experimentally measured \tilde{X}/\tilde{A} branching ratio with the calculated potential energy surfaces.

One of the most puzzling experimental observations has been the fact that the \tilde{X}/\tilde{A} product branching ratio shows the strong resonance-like enhancement at the ν_s mode excitation of $C_6H_5S-CD_3$ giving the \tilde{X}/\tilde{A} product branching ratio of 0.33 ± 0.04 , whereas the ν_s mode excitation is not so effective in facilitating the nonadiabatic transition for $C_6H_5S-CH_3$ to give $I \sim 0.165 \pm 0.025$.^{3,6} This has been considered to be peculiar as such a huge effect of the methyl moiety deuteration on the nonadiabatic dynamics is not anticipated. In this regard, it is quite interesting to find out here that the S_1/S_2 crossing point is calculated to be more accessible by the one quantum of ν_s for $C_6H_5S-CD_3$, Fig. 4(f), whereas it is less likely to be accessible for the case of $C_6H_5S-CH_3$, Fig. 4(e). In other words, the S_1/S_2 crossing point along ν_s is located energetically much higher for $C_6H_5S-CH_3$ compared to that of $C_6H_5S-CD_3$ with respect to their S_1 minima. Moreover, the S_1/S_2 crossing point of $C_6H_5S-CH_3$ is quite remote from the S_1 minimum energy position in terms of the nuclear displacement compared to that of $C_6H_5S-CD_3$. It is indeed remarkable that the simple potential curve calculation could explain the experimental finding very well at least qualitatively. The effect of deuteration of the methyl moiety on the

reaction nonadiabaticity seems to be similarly applicable to isotopomers of $C_6D_5S-CH_3$ and $C_6D_5S-CD_3$ at the ν_s mode excitation, giving the \tilde{X}/\tilde{A} branching ratio of 0.19 ± 0.02 and 0.22 ± 0.06 , respectively. The S_1/S_2 curve crossing points of two isotopomers along ν_s support the experiment, as the crossing point of $C_6D_5S-CD_3$ is predicted to be located lower than that of $C_6D_5S-CH_3$ with respect to the S_1 minima of those isotopomers, Fig. 4(g) and (h). And yet, it should be noted that the \tilde{X}/\tilde{A} branching ratio generally increases slowly with increasing the energy with the different slopes depending on the molecular characteristics.³ In this sense, the \tilde{X}/\tilde{A} branching ratios estimated at the ν_s mode excitations of $C_6H_5S-CH_3$ and $C_6D_5S-CH_3$ are hardly associated with dynamic resonances in the proximity of the conical intersection seam, and thus the explanation of those experimental results based on the potential energy curve crossings seems to be less meaningful at the present time. The dynamic role of the pseudo-conical intersection previously predicted to be existed at the $C-C-S-CH_3$ dihedral angle of 90° ²⁵ has not been considered in this work, while it could be important in the high S_1 internal energy region where the out-of-plane modes are likely to be more activated.

Conclusions

Quantum mechanical characterization of the multidimensional conical intersection seam has been demonstrated to be feasible in predissociation reaction of the excited thioanisole molecule. The projection of the S_1/S_2 conical intersection seam onto the normal mode space could be inferred from the nature of the S_1/S_2 vibronic modes responsible for dynamic resonances showing the large enhancement of the nonadiabatic transition probability. The \tilde{X}/\tilde{A} product branching ratios estimated from the translational energy distributions of the nascent methyl fragments measured for various isotopomers of thioanisole are particularly useful as the proximity of the initial reactive flux to the conical intersection seam could be judged from different viewpoints set by the different normal mode space. Accordingly, the nonadiabatic bifurcation dynamics of the reactive flux into either the Herzberg type-I (electronic) or type-II (vibrational) predissociation pathway has been disentangled and the structure and dynamic role of the conical intersection seam could be inspected from various points of view. With the aid of simple calculations of potential energy curves along selected normal mode displacements, we report the first cornerstone for the otherwise formidable characterization of the conical intersection seam in polyatomic molecular system.
