Recently, the California Department of Public Health issued an advisory related to the substantial rise in Coccidioidomycosis in California, which has been attributed in part to climate change and rapid housing development. Most cases are self-limiting, but some may spread to the meninges, resulting in coccidioidal meningitis (CM). Many providers mistakenly presume that CM is limited to patients who are immunocompromised. In this case series and literature review, we present 12 cases of CM in immunocompetent individuals seen at a single tertiary academic center between 1 January 2019 and 31 December 2023. All 12 cases developed complications, with 10 requiring ventriculoperitoneal shunting, 6 having spinal cord involvement (5 with cervical spine involvement), 4 having strokes, and 3 dying from complications related to CM. It is important to recognize CM as it may be life-threatening if not promptly diagnosed.

Keywords. climate change; coccidioidal meningitis; coccidioides; fungal meningitis; immunocompetence.

Epidemiology

Coccidioidomycosis is a fungal infection caused by *Coccidioides*, a fungus found in soil endemic to areas in the southwestern

Rapid housing development has led to an increase in the incidence of cases. From 1998 to 2011 in Arizona and California, incident cases rose from 5.3 per 100 000 to 42.6 per 100 000 [3]. Earlier this year, the California Department of Public Health issued a health advisory regarding the substantial increase in Coccidioidomycosis, citing 9280 cases, suspected to be due in part to "heavy rainfall in the winter of 2022–2023 following years of drought" [4]. Global warming has been further implicated in the expansion of *Coccidioides* spores into new territories such as Washington state because of warmer and drier climates [5].

Although a review of coccidioidomycosis in immunocompetent patients is presented elsewhere [6], we review the existing literature specific to coccidioidal meningitis (CM), present a chart review of our single-center demographics of 33 CM cases, and provide a case series of 12 immunocompetent individuals (9 males, 3 females) to help guide recognition and management of this potentially life-threatening condition.

METHODS

Literature Review

We conducted a search of the PUBMED database for articles published in English, available as full text, involving human participants, up until 1 June 2024, using the MESH terms "meningitis" AND "coccidioides," excluding preprints. The entries were screened by 3 authors (R.R., J.D., and M.H.) for potential relevance.

Participant Identification

Our institution is an academic tertiary referral center located in Orange County, California, USA. A chart review tool (Slicer Dicer, Epic, Verona, USA) was used to search the electronic medical record for cases of CM using the International Classification of Diseases, revision 10, code for CM (ICD-10-CM: B38.4) between 1 January 2019 and 31 December 2023. Thirty-three cases were identified and 12 cases were directly seen by at least 1 of the physician coauthors and were determined to be immunocompetent at time of initial infection. Institutional review board approval was obtained for this study from the University of California, Irvine institutional review board (protocol # 3352).

Statistical Analyses

Fisher exact test analyses were used to determine if CM prevalence occurred at a greater-than-chance rate based on self-identified race or ethnicity compared to 2021 US census data for racial

^aThese authors contributed equally.

and ethnic demographics in Orange County, California, USA, from the American Community Survey [7].

RESULTS

Literature Review

A total of 59 entries were identified (Figure 1). Forty articles were deemed to be relevant original articles; 18 articles reported at least 1 immunocompetent CM case, 15 did not report on immune status, and 7 had only immunocompromised cases. Supplementary Table 1 contains the complete study list. No studies directly compared immunocompetent cases to immunocompromised cases of CM. Twelve additional review articles are incorporated into the literature review to broaden the discussion of coccidiomycosis for context.

Literature Review: Epidemiology

A total of 89 immunocompetent CM cases were identified. The youngest case was age 23 days [8], most were between age 30 and 60 years, whereas the oldest was age 80 years [9]. A retrospective analysis from southern Arizona revealed that the demographics most affected were men (2:1 male: female ratio) of Asian, African, and Hispanic descent [10].

Literature Review: Clinical Presentations

It is estimated that 95% of pulmonary infections self-resolve, but if the fungus spreads to the central nervous system, it is universally fatal without treatment [1, 11]. Patients can present with symptoms as minor as a mild headache. More serious symptoms include global headaches lasting from weeks to months, cognitive decline, gait disturbances, diplopia, disorientation, lethargy, and/or stupor [1]. On physical examination,

nuchal rigidity is uncommon [1]. Signs of pulmonary or extrapulmonary infection occur in only 1/3 to 2/3 of patients with CM and clinical presentations will depend on these additional sites of infection [1].

Literature Review: Diagnostic Work Up

CM diagnosis relies on cerebral spinal fluid (CSF) or biopsy [12]. In immunocompetent patients, detectable serum immunoglobulin M (IgM) antibody is typically seen within 1 to 3 weeks of symptom onset, followed shortly thereafter by IgG production [13]. Immunodiffusion (ID) and complement fixation (CF) remain the benchmarks, with the former test being more sensitive. A positive CF test for IgG antibody in CSF is considered diagnostic for CM in the setting of a compatible clinical syndrome [14]. High

Table 1. Demographics of Coccidioides Meningitis Cases

	Total CM Cases (n = 33) (%)	Immunocompetent Subset (n = 12) (%)
Age in y: mean (range)	53 (24–86)	34 (21–67)
Female	8 (24)	3 (25)
Male	25 (76)	9 (75)
Asian	6 (19)	2 (17)
Black	3 (9)	2 (17)
Native Hawaiian or Other Pacific Islander	1 (3)	1 (8)
Other Race or Mixed Race	6 (19)	2 (17)
Not stated	1 (3)	0 (0)
White	17 (52)	5 (42)
Hispanic	16 (48)	4 (33)
Non-Hispanic	17 (52)	8 (66)

Abbreviation: CM, coccoides meningitis.

serum titers may "spill over" into CSF, resulting in false-positive ID results for CSF samples. Therefore, CF is the recommended diagnostic modality for CM diagnosis. A serum CF titer greater than 1:32 is concerning for dissemination of the disease [13, 14]. A CSF culture confirms a diagnosis of CM but is typically positive in only 25% of patients [15]. A cellular profile of CSF that would be suggestive of CM may include a lymphocytic, polymorphonuculear neutrophilic, or characteristically eosinophilic pleocytosis [12] with elevated protein, low glucose [1, 11, 12, 16], and elevated opening pressure. Diagnostic techniques that have not been thoroughly validated should be avoided, including measuring (1,3)-β-glucan in serum, antibody enzyme immunoassays, lateral flow tests [1, 11], and polymerase chain reaction for presence of fungal nucleic acid [17]. Hydrocephalus may be seen on noncontrast head computed tomography [18], whereas magnetic resonance imaging may show leptomeningeal enhancement and nodularity [1, 16].

Literature Review: Effective Treatments

Treatment was revolutionized in the 1990s when thirdgeneration azoles were proven to be effective in managing CM [12]. Nonetheless, azoles are fungistatic agents and lifelong treatment is required. The most common primary treatment for CM is fluconazole at 400–1200 mg daily, but there is no consensus for the starting dose [12]. Azoles should also be avoided in patients in the first trimester of pregnancy because of teratogenicity [11, 12]. Adjunctive treatments include corticosteroids, which were associated with a significant reduction in secondary cerebrovascular events in a multicenter retrospective cohort [19]. A coccoides vaccine remains elusive [20, 21].

Chart Review Demographics

Demographic comparisons of the 33 cases identified through chart review and the 12 immunocompetent cases is provided in Table 1. The number of new cases remained stable across the 5-year period with an average of roughly 3 new cases/year (± 2) (Supplementary Figure 1). Fifteen cases (45%) occurred in patients who were between age 18 and 50 years and 18 were >50 (55%) with a median age of 53 (\pm 16) years. However, this represents the patients' current age and the age of infection onset could not be determined from this method. Twenty-five patients were male and 8 were female (roughly 3:1). A total of 52% of patients self-identified as White, 19% as Other/Mixed race, 19% as Asian, 9% as Black, and 3% as Native Hawaiian or Pacific Islander (Supplementary Figure 2). Forty-eight percent identified as Hispanic and 52% as non-Hispanic (not pictured). Geographic distribution by postal code of residence for cases is presented in Figure 2.

Immunocompetent Cases

Twelve participants directly assessed by the physician authors were determined to be immunocompetent. All 12 had nonreactive HIV serum studies. A summary of these cases is provided in Table 2. The median age of symptom onset was $34 (\pm 15 \text{ years};$ range, 21–67) years. There were 9 males and 3 females. Two cases endorsed exposure to a construction site where excavation was ongoing. One had known celiac disease with no evidence of immunocompromise on diagnostic studies or history of treatment with immunomodulatory therapies. The 9 remaining cases had no clear predisposing condition or exposure risk.

Eight of 12 (67%) presented with the classic triad of hydrocephalus (headaches, confusion, and vomiting). Of the 4 without the classic triad, 2 presented with headache and oculomotor nerve deficits, 1 with neck pain, and 1 with progressive asymmetric weakness. Three of 7 had evidence of hydrocephalus on the first head computed tomography acquired. Two of 5 who underwent noncontrast head computed tomography scan at the time of having the classic triad did not show evidence of hydrocephalus. All 12 cases developed complications,

with 10 requiring ventriculoperitoneal shunting, 6 having spinal cord involvement (5 with cervical spine involvement), 4 having strokes, and 3 dying from complications related to CM. All patients were treated with antifungal agents. Information on treatment initiation was available for 5 cases. The median time to treatment initiation was 12 weeks (\pm 6) but was 16 weeks for those with an age of symptom onset >50 compared to 6 weeks for those <50. The 3 cases with an age of symptom onset >50 passed away, whereas all others have survived. Two of these patients died in the subacute setting because of recurrent strokes secondary to basilar meningitis, whereas the third died from recurrent infections and medical complications secondary to quadriplegia from coccoides myelitis 11 years after the initial infection.

Table 3 provides a comparison of racial and ethnic demographics from US census data of Orange County to our total CM cases. Self-identified race or Hispanic ethnicity was not associated with a higher than chance probability of infection.

DISCUSSION

We note that immunocompetent cases had similar demographics to the total number of CM cases. In both groups, there was a 3:1 male: female ratio, with a majority of cases occurring in males between ages 20 and 70 years, similar to the male:female ratio of CM cases observed by others [10]. Unlike prior reports, we did not see a greater-than-chance prevalence of CM cases for those who identified as Asian or Hispanic [10]. The majority of patients presented with classic symptoms of hydrocephalus. Among our immunocompetent group, neuroimaging demonstrated signs of hydrocephalus 12 weeks after symptom onset on average. The nonspecific nature of initial presentation is unfortunate because CM has a number of serious complications, including quadriparesis from syringomyelia, refractory hydrocephalus, recurrent strokes, and death.

The time between symptom onset to initiation of treatment was largely dependent on timing of diagnosis. Although advanced age may be associated with poorer prognosis, it is important to note that the median time to initiation of treatment for those age <50 years was 6 weeks versus 16 weeks for those age >50 years. This highlights the importance of improving physician awareness of hydrocephalus and CM in elderly patients who present with nonfocal complaints because this 10-week delay may be a critical period in preventing the formation of life-threatening basilar meningitis. Fungal infections of immunocompetent individuals are not limited to *Coccidioides*. A large prospective cohort study has looked at cryptococcal infection of HIV-negative patients and noted significant sequelae of infection [22].

A strength of this investigation is that it is, to our knowledge, the first case series to review CM infections specifically in immunocompetent individuals. Three other case series were identified that had sizeable immunocompetent CM populations $(\geq 10 \text{ cases})$ [10, 23, 24]. Demographic information on these subgroups was not reported, prohibiting comparisons to immunocompromised groups or to our data. Limitations include that this is a single-center study and the lack of an immunocompromised comparison group. Our institutional review board protocol restricted our review of cases not directly assessed by the physician authors to anonymized data. We cannot determine if the patients contracted the infection in the same place as their residence (Figure 2). Other healthcare networks exist in our county, and this may bias the demographics of the patients seen. Several cases presented for acute management and lacked sufficient records to determine their initial examination findings.

We exercise caution in interpreting our findings with regard to demographics. It remains possible that immunocompetent patients may have predisposing genetic conditions that were not identified. We emphasize that epidemiological investigations to understand differences in risk factors, pathogenesis, presenting symptoms, and response to treatment across diverse populations should remain a priority to ensure equitable care in the face of a growing prevalence of the disease. Future studies should assess for differences in clinical findings and disease progression between immunocompetent and immunocompromised patients with CM.

CONCLUSION

It is a common misconception that CM is an opportunistic infection. We discuss our single-center experience within the context of the existing literature to improve early diagnosis and management for common complications of this life-threatening disease. This is of particular importance as large-scale construction projects for housing development throughout the southwestern United States may lead to the release Cocci spores from the soil and to further infections with compounding concerns of more severe weather extremes brought on by global warming expanding the endemic territory of *Coccidioides*.

Supplementary Data

Supplementary materials are available at *Open Forum Infectious Diseases* online. Consisting of data provided by the authors to benefit the reader, the posted materials are not copyedited and are the sole responsibility of the authors, so questions or comments should be addressed to the corresponding author.

Notes

Acknowledgments. Not applicable.

Author Contributions. R.R. provided conceptual framework for the manuscript, contributed to manuscript text and figure design, and critically revised the article. M.H. and J.S.D. drafted the article along with figure design. K.G.A., G.F., and J.D. obtained patient information and contributed to the text. N.C., C.D., and X.L. contributed to the conceptual framework and critically revised the manuscript. Neither chatbots nor artificial intelligence was used for any portion of this work.
