# Reduction in Pain and Inflammation Associated With Chronic Low Back Pain With the Use of the Medical Food Theramine

William E. Shell, MD, Stephanie Pavlik, CRA, Brandon Roth, Michael Silver, Mira L. Breitstein, CRA, Lawrence May, MD, and David Silver, MD\*

Management of chronic back pain is a challenge for physicians. Although standard treatments exert a modest effect, they are associated with narcotic addiction and serious side effects from nonsteroidal antiinflammatory agents. Moreover, neurotransmitter depletion from both the pain syndrome and therapy may contribute to a poor treatment outcome. Neurotransmitter deficiency may be related both to increased turnover rate and inadequate neurotransmitter precursors from the diet, particularly for essential and semi-essential amino acids. Theramine, an amino acid blend 68405-1 (AAB), is a physician-prescribed only medical food. It contains neurotransmitter precursors and systems for increasing production and preventing attenuation of neurotransmitters. A double-blind controlled study of AAB, low-dose ibuprofen, and the coadministration of the 2 agents were performed. The primary end points included the Roland Morris index and Oswestry disability scale. The cohort included 122 patients aged between 18 and 75 years. The patients were randomized to 1 of 3 groups: AAB alone, ibuprofen alone, and the coadministration of the 2 agents. In addition, C-reactive protein, interleukin 6, and plasma amino acid concentrations were measured at baseline and 28 days time points. After treatment, the Oswestry Disability Index worsened by 4.52% in the ibuprofen group, improved 41.91% in the AAB group, and improved 62.15% in the combination group. The Roland Morris Index worsened by 0.73% in the ibuprofen group, improved by 50.3% in the AAB group, and improved 63.1% in the combination group. C-reactive protein in the ibuprofen group increased by 60.1%, decreased by 47.1% in the AAB group, and decreased by 36% in the combination group. Similar changes were seen in interleukin 6. Arginine, serine, histidine, and tryptophan levels were substantially reduced before treatment in the chronic pain syndrome and increased toward normal during treatment. There was a direct correlation between improvement in amino acid concentration and treatment response. Treatment with amino acid precursors was associated with substantial improvement in chronic back pain, reduction in inflammation, and improvement in back pain correlated with increased amino acid precursors to neurotransmitters in blood.

*Keywords:* pain, inflammation, Theramine, AAB, medical food, amino acid, low back, ibuprofen

## INTRODUCTION

The diagnosis and management of back pain is a challenge for both primary care physicians and specialists. Establishing an etiology can be difficult and often

problematic given treatment options that may be capable of producing serious and potentially life-threatening side effects. Treatments in some individuals often may exert a modest impact on the natural history of the condition.<sup>1–3</sup> Nonsteroidal antiinflammatory drugs (NSAIDs)

are frequently prescribed to treat chronic back pain, while they are only moderately effective in relieving pain<sup>4-7</sup> and are associated with significant side effects. Muscle relaxants and opioid analgesics show limited efficacy and may produce sedation, constipation, or inappropriate usage. Newer antiepileptics and serotonin–norepinephrine reuptake inhibitors have been shown to decrease pain but have limitations. Physical therapy and other local modalities may augment treatment costs and require a considerable investment of patient time.

Neurotransmitter depletion<sup>8-14</sup> and the associated synaptic fatigue<sup>15-22</sup> may contribute to chronic pain states. Neurotransmitter depletion results from an increase in precursor turnover and dietary deficiency of the precursor.<sup>23-28</sup> The ability to enhance neurotransmitter production associated with pain syndromes has multifactorial limits. Specifically, the unavailability of adequate essential amino acids in the diet and increased turnover rates of amino acids needed to produce neurotransmitters under such conditions.<sup>23-28</sup> Table 1 explains how Theramine, an amino acid blend 68405-1 (AAB) addresses this unavailability. In addition, amino acids are over 99% deaminated by the liver before crossing the blood brain barrier and may not be taken up by the appropriate neuron. Once in the neuron, the adenosine brake must be released and the attenuation of effect after a couple of weeks is common. Other factors such as prolonged pharmaceutical use deplete the nerve cells of neurotransmitters.<sup>29-34</sup>

Previous attempts<sup>35-38</sup> to modify brain neurochemistry have focused on single neurotransmitters, such as serotonin or GABA and have not addressed the secondary issues. This approach fails to tackle the complexity of complementary neurotransmitters and their influence on patient perception of pain and suffering. AAB is a proprietary prescription medical food that concurrently enhances several neurotransmitters that are involved in pain modulation and sensation by providing neurotransmitter precursors in the form of amino acids (Table 1).<sup>41</sup> Through a 5-step process, AAB prevents deamination by the liver, promotes uptake into the appropriate neuron, conversion to the neurotransmitter, releases the adenosine brake, and

prevents the attenuation of effect. Medical foods<sup>42</sup> are specially formulated products for the specific dietary management of a disease or condition that has distinctive nutritional requirements. Nutrient imbalances caused by pain leads to metabolic disequilibrium. The nutrients and other dietary ingredients in AAB are specifically selected and processed molecular complexes derived from foods. These components have scientifically documented properties that support the cellular or physiological activities needed to restore metabolic equilibrium, proportioned to stimulate the production of neurotransmitters in targeted cells. Clinical trials have found AAB effective in reducing and modifying pain without demonstrable side effects. AAB simultaneously stimulates the production of the neurotransmitters serotonin, GABA, nitric oxide, glutamate, and histamine.

In a previous study comparing AAB and low-dose naproxen, both the medical food group and combined therapy group (AAB with naproxen) showed statistically significant functional improvement compared with the naproxen-alone group ( $P < 0.05$ ) at the 28 days time point. Furthermore, the naproxen-alone group showed significant elevations in C-reactive protein (CRP) (an acute phase marker of inflammation), alanine transaminase, and aspartate transaminase when compared with the other groups. AAB alone or in combination with naproxen showed no significant change in liver function or inflammation tests, with potentially mitigating the effects seen with naproxen alone. AAB seemed to be effective in relieving back pain without causing any significant side effects and may provide a safe alternative to presently available therapies.<sup>41</sup>

This research protocol compared AAB to a low-dose NSAID in the treatment of chronic low back pain as defined by pain lasting greater than 6 months and present on at least 5 of 7 days per week. The low-dose NSAID was used as it was not felt that the use of strictly placebo was appropriate in a chronic pain study, while the authors did not wish to expose patients to the risks associated with full dose NSAID use.

Ibuprofen is the most commonly used and most frequently prescribed NSAID.<sup>2,3</sup> It is a nonselective inhibitor of cyclooxygenase-1 and cyclooxygenase-2.<sup>4</sup> It has

**Table 1.** Neurotransmitter production from precursors.

Amino acid precursor	Neurotransmitter	Physiological effect
Choline	Acetylcholine	Decreases pain perception; inhibits pain
L-Histidine	Histamine	Inhibits inflammation
5-OH-Tryptophan	Serotonin	Inhibits inflammation
Serine	D-Serine	Increases sensitivity to opioids
Arginine	Nitric oxide	Produces natural opioids

a prominent analgesic and antipyretic role despite its antiinflammatory properties being weaker than those of some other NSAIDs. These effects are due to the inhibitory actions on cyclooxygenases, which are involved in the synthesis of prostaglandins. Prostaglandins have an important role in the production of pain, inflammation, and fever.<sup>5</sup> The study examined the efficacy and tolerability of AAB in patients with chronic back pain compared to ibuprofen, and the combination of ibuprofen and AAB together.

## MATERIALS AND METHODS

The study involved 122 patients aged between 18 and 75 years in a double-blind, randomized, 3-armed trial comparing ibuprofen alone (400 mg daily), AAB alone (two 355 mg capsules twice daily), or the combined use of ibuprofen (400 mg daily) and AAB (two 355 mg capsules twice daily) for 28 days. On day 1 visit, patients were randomized to 1 of 3 groups: (1) two AAB tablets, 2 times per day, with 1 ibuprofen placebo, (2) ibuprofen (400 mg once per day), with 2 AAB placebos, 2 times per day, and (3) two AAB tablets, 2 times per day, with ibuprofen (400 mg once per day). The active and ibuprofen tablets were identical, and the active AAB and placebo capsules were identical. On days 7 and 14 visits, the evaluation of visual analog scale (VAS) and patient medication usage were completed. On day 28 visit, a Roland–Morris Disability Questionnaire, an Oswestry Low Back Pain Scale, a VAS evaluation, and a patient medication usage evaluation were completed. Blood was again sampled for estimating CRP, blood count, and blood chemistries.

## INCLUSION CRITERIA

Patients were identified in 8 separate clinical sites that were selected through an independent contract research

organization that provides experienced investigators for clinical study selection (Table 2). Men and nonpregnant nonlactating women aged between 18 and 75 years were recruited for the study. To be included in the study, subjects were required to have back pain lasting longer than 6 weeks, with pain present on 10 of 14 days before screening. Subjects with a Roland–Morris back pain index 40 of 100 mm on the VAS were included. Subjects included must have used analgesic medication to treat pain at least 4 of last 7 days and at least 10 days in the last month before the study. Those taking an NSAID for pain had to discontinue use during a wash-out period based on the attached 5 half-lives of drug chart. If undergoing physical therapy for back pain, therapy had to have been stable at least 3 weeks before study and remained the same throughout study. If using psychoactive medication that might have analgesic effects (ie, antidepressants or anticonvulsants), treatment must have been stable for at least 3 months before study. Men and women of childbearing potential were required to use adequate contraception and not be pregnant or impregnate their partner during the entire duration of the study. All selected subjects were willing to commit to all clinical visits during study-related procedures, including required discontinuation washout period of analgesic or antiinflammatory medication before day 1 randomization. Finally, subjects agreed to the use of acetaminophen for rescue medication.

## EXCLUSION CRITERIA

Subjects were excluded if they were not fluent in English. Subjects who underwent surgery in the previous 6 months were excluded as were subjects with neurologic impairment. Subjects with fracture of the spine within the past year and patients receiving oral, intramuscular, or soft tissue injection of corticosteroids within 1 month before screening were excluded. Subjects were not selected who used more than 325 mg of

aspirin daily for nonarthritic conditions, and stability for 1 month before screening was required for any usage. Subjects were also excluded if they had a history of gastrointestinal (GI) bleeding, gastric or duodenal ulcer as were subjects receiving an epidural injection within the 3 months before screening. Individuals with a history of alcohol or substance abuse, uncontrolled or unstable serious cardiovascular, pulmonary, GI, or urogenital, endocrine, neurologic, or psychiatric disorder were not included. Subjects were also excluded for participation in a previous clinical trial within 1 month of screening for the present study. Finally, subjects who used controlled substances or opiate analgesics for 5 days in the month before screening were considered ineligible to participate.

## RESULTS

Among the 3 groups, there was no statistical difference in low back pain, inflammation, or any of the efficacy and safety variables assessed at baseline (Table 3), according to the primary end points of the Roland–Morris Disability Questionnaire and the Oswestry Disability Index. At day 28 (Table 4), both the AAB group and combined therapy group (AAB with ibuprofen) pain assessment indices were considerably and statistically significantly improved compared with the ibuprofen-alone group ( $P < 0.05$ ). The Roland–Morris Index fell by 63.1% (Figure 1), and the Oswestry Disability Index fell 62.15% (Figure 2) between baseline and day 28 in the AAB + ibuprofen group. In the AAB-alone group, the Roland–Morris Index fell by 50.3%, and the Oswestry Disability index fell 41.91% between baseline and day 28. Thus, if AAB was used as either primary therapy or an adjunct to ibuprofen, low back pain was significantly improved. Ibuprofen alone had no appreciable effect on chronic back pain within 28 days. Similar results were seen on using the VAS scale.

Secondary end points included CRP, interleukin 6 (IL-6), and plasma amino acid levels at day 28

compared with baseline (Figures 3, 4). In the ibuprofen-alone group, CRP rose by 60.1% ( $P < 0.001$ ), and IL-6 rose by 12.65% ( $P < 0.001$ ). In the AAB-alone group, the CRP level fell by 47.05% ( $P < 0.05$ ), and IL-6 level fell by 23.55% ( $P < 0.01$ ). In the group treated with both the AAB and ibuprofen, CRP fell 35.99% ( $P < 0.001$ ), and IL-6 fell 43.1% ( $P < 0.001$ ). Plasma amino acids were analyzed with liquid chromatography–tandem mass spectrometry methodology (Figure 5). The assay had a variance of  $\pm 5\%$ . Arginine concentration levels at day 1 were at 13.5  $\mu\text{g}/\text{mL}$ , rising to 21.8  $\mu\text{g}/\text{mL}$  at day 28 of the study, where normal level is 30  $\mu\text{g}/\text{mL}$ . Serine concentration levels at day 1 were 5.4  $\mu\text{g}/\text{mL}$ , which rose to 17.8  $\mu\text{g}/\text{mL}$  at day 28 of the study, where normal is 21.5  $\mu\text{g}/\text{mL}$ . Histidine concentration levels at day 1 were at 6.2  $\mu\text{g}/\text{mL}$ , which rose to 14  $\mu\text{g}/\text{mL}$  at day 28 of the study, where normal is 15.2  $\mu\text{g}/\text{mL}$ . Tryptophan concentration levels at day 1 were at 4.1  $\mu\text{g}/\text{mL}$ , which rose to 17  $\mu\text{g}/\text{mL}$  at day 28 of the study, where normal is 19.5  $\mu\text{g}/\text{mL}$ . Use of breakthrough medication was highly statistically significantly lower in the AAB, and the combination AAB/ibuprofen groups when compared to ibuprofen alone (Figure 6).

The range for normal subjects was established by ranges supplied from quest laboratories for this study. There were no adverse events or complications among any of the groups during this 28-day study (Table 5). There were no GI side effects observed in this cohort (Figure 6).

## DISCUSSION

Back pain is a common concern, affecting up to 90% of people during their lifetime. NSAIDs are the most frequently used drugs in the treatment of pain and inflammation. However, their use is limited by adverse drug side effects, notably GI toxicity. Many of the adverse effects are dose related. The current recommendation of the American Geriatrics Society

is to restrict or even eliminate NSAIDs in patients, specifically when older than 65 years. This demographic has the highest incidence of osteoarthritis, back pain, and spinal stenosis. Although they are at greatest risk for adverse events, often their only alternative to NSAIDs are narcotics, which carry additional side effects and risks.

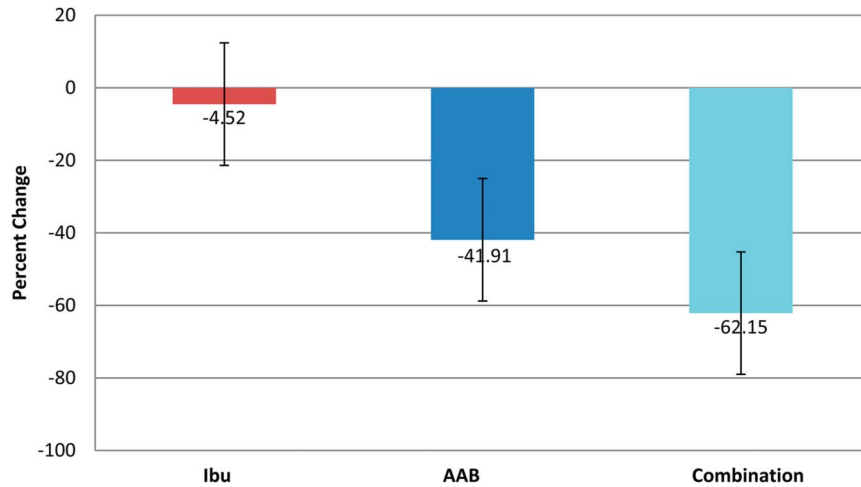

Antiinflammatory nonsteroidal drugs with nitric oxide (NO)-producing precursors (NO-NSAIDs) are a new class of drugs. These compounds have been shown to retain the antiinflammatory, analgesic, and antipyretic activity with reduced GI toxicity. The use of an NO moiety with an NSAID has been shown to inhibit *in vitro* T-cell proliferation and cytokine

production.<sup>43</sup> NO-NSAIDs have been shown to be GI protective in several models. AAB produces NO similarly to the NO-NSAIDs.<sup>43</sup> It is interesting to note that tryptophan induces an increase in platelet aggregability, and NO production in the GI tract is known to reduce NSAID-induced mucosal erosion.

The amino acid formulation (AAB) of neurotransmitter precursors used in this study is designed to elicit neurotransmitter production of neurotransmitters that modulate nociception and inflammation.<sup>41</sup> The precursors of serotonin, nitric oxide, histamine, and GABA are supplied in this formulation as 5-hydroxytryptophan (5-HTP), arginine, histidine, and glutamine, respectively.

**FIGURE 1.** Percent change in Roland Morris Disability Questionnaire Pain Scale from day 1 to day 28. Ibu n = 43, AAB n = 41, and combination n = 38. Roland Morris Disability Index fell 63.1% between baseline and day 28 in the combination therapy group, and fell 50.3% in the AAB-alone group, while there was no significant effect on chronic back pain in the ibuprofen-alone treatment group.

**FIGURE 2.** Percent change in Oswestry Disability Index from day 1 to day 28. Ibu n = 43, AAB n = 41, and combination n = 38. Oswestry Disability Index fell 62.15% between baseline and day 28 in the combination therapy group, and fell 41.91% in the AAB-alone group, while there was no significant effect on chronic back pain in the ibuprofen-alone treatment group.

To test the hypothesis that chronic back pain syndromes have an amino acid deficiency emanating from increased amino acid requirements that cannot be met by normal diet, we measured plasma amino acid concentrations at day 1 and day 28. Day 1 blood levels of amino acid neurotransmitter precursors in AAB-treated subjects were more than 2 SDs below the mean for normal subjects. Thus, in this cohort of patients with a chronic back pain syndrome, there is a deficiency of amino acid precursors in plasma that are important to neurotransmitters modulating chronic pain. Because these patients were on normal diets, study data indicate that normal diet alone cannot

sustain the amino acid requirements of this chronic back pain syndrome. There do not seem to be any other studies that establish a nutrient deficiency of pain-related neurotransmitters.

Subjects who increased their amino acid blood levels in response to AAB administration over 28 days, demonstrated a reduction in pain as measured by the Roland Morris Disability Questionnaire, a reduction of disability symptoms as measured by the Oswestry Disability Index, and inflammation as measured by a reduction in CRP. Subjects who were treated with once a day ibuprofen did not increase their amino acid concentration, did not improve clinically, and demonstrated

**FIGURE 3.** Percent change in CRP from day 1 to day 28. Ibu n = 43, AAB n = 41, and combination n = 38. The CRP levels fell 35.99% for combination therapy group and 47.05% for the AAB-alone group, while levels rose 60.1% for the ibuprofen-alone group.

**FIGURE 4.** Percent change in IL-6 from day 1 to day 28. Ibu n = 43, AAB n = 41, and combination n = 38. The IL-6 levels fell 43.1% for combination therapy group and 23.55% for the AAB-alone group, while levels rose 12.65% for the ibuprofen-alone group.

increased inflammation. Four of 41 subjects treated with AAB did not increase their blood concentration of amino acid, improve their clinical responses, or reduce inflammation. This may be because of minimal dosing or noncompliance.

The AAB-alone group produced a 50.3% reduction in the Roland–Morris Index and a 41.91% reduction in the Oswestry index. The AAB with 400 mg of ibuprofen

administered once a day resulted in a 63.1% reduction in the Roland–Morris Index and a 62.15% reduction in the Oswestry Index. A single daily dose of 400 mg of ibuprofen had no significant effect on chronic back pain over 28 days, a nonsignificant 0.73% increase in the Roland–Morris Index measure of pain was found. Although the number of subjects was limited to 122, the differences in the data were statistically highly

**FIGURE 5.** Plasma amino acid concentrations were calculated at day 1 and day 28 in 44 of 122 patients. Plasma amino acids were analyzed using liquid chromatography–tandem mass spectrometry methodology. The assay had a variance of ±5%.

**FIGURE 6.** The needed breakthrough medication usage was statistically significant in the AAB group versus the ibuprofen-alone group.

significant. However, since the ingredients of AAB are generally recognized as safe according to the FDA, a large safety trial is seemingly unnecessary.

This evidence is supported further by a double-blind controlled trial of a single dose naproxen and AAB for the treatment of low back pain.<sup>41</sup> This study also indicated a reduction in pain with the Roland–Morris Index by 65%, and the Oswestry Disability Index by 61% between baseline and day 28 in the AAB + naproxen group. In the AAB-alone group, there was a significant reduction in back pain with a 32.94% on the Oswestry Disability Index and a 44% on the Roland–Morris Index. Thus, if AAB was used as either primary therapy or an adjunct to naproxen, low back pain was significantly improved. Low-dose naproxen had no significant effect on chronic back pain in 28 days. Similar results were seen on using the VAS scale.

Treating the metabolism-based nutritional deficiencies of pain syndromes could allow for the reduction of NSAID use without affecting therapeutic efficacy. Dietary management of disease is an underutilized

option for patients, although it has existed for a considerable period of time. Osler<sup>44</sup> prominently emphasized the value of nutrition in his textbooks. Tepaske et al administered an arginine-based preparation to patients before cardiac surgery.<sup>39</sup> The clinical outcomes were found to be improved, more specifically postoperative creatinine clearance and immune function. Kalantar-Zadeh et al<sup>40</sup> and Tepaske et al<sup>39</sup> determined that the administration of amino acid neurotransmitter precursors in patients with congestive heart failure improved clinical outcomes. Advances in science mandate the inclusion of nutrient management of symptoms and disease.

Levels of CRP increase very rapidly in response to trauma, inflammation, and infection and decrease just as rapidly with the resolution of the condition. Thus, the measurement of CRP is widely used to monitor various inflammatory states. Baseline levels of inflammation are associated with one another and with future risk of coronary heart disease. This reduction in CRP has been demonstrated in the naproxen and AAB study as well. With CRP’s association with

**Table 5.** Percent change in blood values in all treatment groups at completion as compared with baseline.

Treatment group	ALB	ALK	ALT	AST	Bilirubin (total)	GGT	Globulin	LDH	Total protein
Ibuprofen	−4.27	−3.58	−2.69	−3.22	5.31	−5.97	0.91	−1.76	−1.98
AAB	−0.40	0.23	−11.46	−2.61	−6.64	−10.18	1.95	2.25	0.62
Combination	−2.04	−4.23	−8.13	−1.24	9.49	−7.03	0.07	0.93	−1.11

There were no adverse events or complications among any of the groups during this 28-day study. No GI symptomatic side effects were observed or reported by participants.

ALB, albumin; ALK, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate transaminase; GGT, gamma-glutamyl transferase; LDH, lactate dehydrogenase.

inflammation, and subsequent involvement as a marker for heart disease, a question arises as to whether AAB may have a cardio protective application. Further investigation into this possible protective effect of AAB is warranted.

IL-6 is a pleiotropic cytokine. In addition to its typical role in the acute phase response, IL-6 is involved in driving chronic inflammation, autoimmunity, endothelial cell dysfunction, and fibrogenesis. Because IL-6 has been associated with the generation and propagation of chronic inflammation, it was selected as a marker in the study. Proinflammatory cytokines from acute inflammation promote neutrophil build up and the release of IL-6<sup>45</sup>. In the study, IL-6 followed the same pattern as CRP, with an increase in level of IL-6 in the ibuprofen-alone group (12.65%), a drop in IL-6 level in the AAB-alone group (23.55%), and a drop in the level of IL-6 in the AAB and ibuprofen group (43.1%).

There are limited data to indicate that the provision of neurotransmitter precursors alters the efficiency of pharmaceuticals. The data in this study indicate that the provision of amino acid precursors in a formulation (AAB) to facilitate neurotransmitter production results in improving the efficiency of pharmaceutical therapy. We postulate that the mechanism is related to improve intracellular metabolic function, rather than having any effect on the drug itself. This may be a new approach to a long-standing therapy.
