Background: Biliary atresia (BA) is a childhood liver disease characterized by fibrous obstruction and obstruction of the extrahepatic biliary system and is one of the most common and serious biliary disorders in infants. Significant inflammation and fibrosis of the liver and biliary tract are the most prominent features, regardless of the initial damage to the BA. Abnormalities in innate or adaptive immunity have been found in human patients and mouse models of BA. We previously reported that children with BA had abnormal lipid metabolism, including free serum carnitine.

Objective: To study gene and protein expression levels of the hepatic peroxisome proliferator-activated receptor- α (PPAR α) signaling pathway and farnesoid X receptor (FXR) in BA and BA fibrosis, and assess their clinical values.

Methods: Low expression of PPAR α and NR1H4 (FXR) in BA were validated in the Gene Expression Omnibus database. Functional differences were determined by gene set enrichment analysis based on of PPAR α and NR1H4 expression. BA patients from GSE46960 were divided into two clusters by using consensus clustering according to PPAR α , NR1H4, and SMAD3 expression levels, and immunoinfiltration analysis was performed. Finally, 58 cases treated in our hospital were used for experimental verification. (IHC: 10 Biliary atresia, 10 choledochal cysts; PCR: 10 Biliary atresia, 14 choledochal cysts; WB: 10 Biliary atresia, 4 choledochal cysts).

Results: Bioinformatics analysis showed that the expression of PPAR α , CYP7A1 and NR1H4 (FXR) in the biliary atresia group was significantly lower than in the control group. More BA-specific pathways, including TGF β signaling pathway, P53 signaling pathway, PI3K-AKT-mTOR signaling pathway, etc., are enriched

in BA patients with low PPAR α and NR1H4 expression. In addition, low NR1H4 expression is abundant in inflammatory responses, IL6/STAT3 signaling pathways, early estrogen responses, IL2 STAT5 signaling pathways, and TGF β signaling pathways. The TGF β signaling pathway was significant in both groups. According to the expression of PPAR α , NR1H4 and SMAD3, a key node in TGF β pathway, BA patients were divided into two clusters using consensus clustering. In cluster 2, SMAD3 expression was high, and PPAR α and NR1H4 expression were low. In contrast to cluster 1, immune cell infiltration was higher in cluster 2, which was confirmed by immunohistochemistry. The mRNA and protein levels of PPAR α and NR1H4 in BA patients were lower than in the control group by immunohistochemistry, Western blot analysis and real-time PCR.

Conclusions: The downregulation of PPAR α and NR1H4 (FXR) signaling pathway may be closely related to biliary atresia.

biliary atresia, bioinformatics, PPAR α , NR1H4, immune microenvironment

Introduction

Biliary atresia (BA) is an inflammatory biliary tract disease characterized by inflammation, fibrosis, and biliary tract obstruction; it is one of the most common severe biliary tract diseases diagnosed in infancy. This progressive disease has unknown etiology, but congenital or acquired immune abnormalities have been found in BA patient samples and mouse models (1, 2). Even with surgery and various immunosuppressive treatments, intrahepatic lesion progression cannot be effectively halted (3). According to Japan's 20-year national biliary registry, which began in 1989, the self-liver survival rate is only 49%, and the surgical success rate depends on the age of the child. The 20-year overall survival rate after liver transplantation is 89%, and the overall rate of good prognosis after transplantation has improved to 97% since 2002 (4, 5). Although liver transplantation can save children's lives, long-term immunosuppressant use and associated complications seriously affect patient quality of life. Early surgery is considered critical for postoperative jaundice relief and autohepatic survival (6).

We previously reported that pediatric BA patients have abnormal lipid metabolism such as free serum carnitine (7, 8). Carnitine is an important carrier of fatty acids; its metabolism, absorption, and utilization are regulated by the peroxisome proliferator-activated receptor alpha (PPAR α) signaling pathway, and it enters cells under the action of the transporter OCTN2 (9). Impaired activation of PPAR α signaling reduces carnitine utilization and bile acid synthesis and secretion, leading to activation of Nuclear Receptor Subfamily 1 Group H Member 4 (NR1H4, also known as farnesoid X receptor

[FXR]) in the liver. NR1H4 (FXR) participates in hepatocyte glucose and lipid metabolism and also inhibits inflammation, fibrosis, and apoptosis (10, 11). The use of glucocorticoids, ursodeoxycholic acid, and other adjuvant therapies after Kasai surgery can increase bile secretion to improve the therapeutic effect (12). The combination of the NR1H4 (FXR) agonist obeticholic acid and a ubiquitin-like inhibitor may significantly inhibit the activation of hepatic stellate cells and inhibit liver fibrosis (11).

Innate immunity also plays a very important role in BA development and can serve as a therapeutic target (13). Cholesterol 7 α -hydroxylase (CYP7A1) is the rate-limiting enzyme for bile acid formation, and bile secretion is also regulated by PPAR α and FXR signaling. The PPAR α pathway regulates bile acid formation and secretion *via* fibroblast growth factor 21, and it increases bile acid production by enhancing CYP7A1 activity in the classical pathway of bile acid anabolism. PPAR α also upregulates the expression of multidrug-resistant protein 3 (MDR3) on the hepatocyte membrane and promotes the excretion of bile acids and bile lipids (10, 14). Under the action of carnitine palmitoyltransferase 1 (CPT1A), which is the rate-limiting enzyme for fatty acid oxidative degradation in the outer mitochondrial membrane, carnitine binds to long-chain fatty acyl-CoA to form long-chain acyl-carnitine. In BA patients, PPAR α signaling pathway activation is impaired; carnitine utilization, bile acid synthesis, and secretion are reduced; and blood carnitine is increased. It is also speculated that bile synthesis and secretion are reduced, which prevents bile acids from activating FXR signaling and suppressing inflammation and fibrosis.

Here we investigated the roles of PPAR α and NR1H4 (FXR) in these pathogenic processes. We analyzed BA transcriptome

profiling data from the Gene Expression Omnibus (GEO) database to comprehensively understand the role of PPAR α and NR1H4 (FXR) in disease immunity. Patient samples were divided into two groups according to PPAR α and NR1H4 (FXR) expression, and bioinformatics techniques were used to compare differences in biological pathways. Immune cell infiltration assays and real-time polymerase chain reaction (PCR) were performed to verify the findings. Consensus clustering was used to divide BA patients in the GSE46960 dataset into two groups: cluster 1 (low expression of SMAD3, high expression of PPAR α and NR1H4) and cluster 2 (high expression of SMAD3, low expression of PPAR α and NR1H4). Our results indicate that patients in cluster 2 have high levels of immunologically infiltration and are better suited for immunotherapy.

Materials and methods

Data acquisition and organization

The BA transcriptome dataset GSE46960 was obtained from the public Gene Expression Omnibus (GEO) database; it included liver tissue from 64 cases of BA, 14 non-BA patients with intrahepatic cholestasis, and 7 normal samples (control). The differentially expressed genes of BA liver tissues (64 cases) and control group liver tissues (21 cases) were compared and analyzed with online GEO2R software. Histograms for the two groups were drawn according to the expression levels of PPAR α , OCTN2, CPT1A, CYP7A1, MDR3, and NR1H4 (FXR). Differences were considered significant at $P < 0.05$.

Gene enrichment analysis

According to previous studies, free carnitine in BA patients can be used to diagnose BA, while PPAR α and NR1H4 (FXR) are key genes in the PPAR signaling pathway and bile acid metabolism (7) with significantly reduced expression in BA. Gene set (h.all.v7.4.symbols.gmt) was used for gene set enrichment analysis (GSEA), which is a computational method that determines whether an *a priori* defined set of genes shows statistically significant, concordant differences between two biological states (15), which was performed for PPAR α and NR1H4 (FXR) expression. Potentially involved signaling pathways were evaluated, and their molecular mechanisms in BA development were investigated.

Gene expression was divided into high and low groups according to median PPAR α and NR1H4 (FXR) expression levels, and 1000 times set sequences were performed for each analysis. The expression levels of PPAR α and NR1H4 (FXR) are given as the normalized enrichment score (NES), normalized significance level (nominal P value), and adjusted multiple hypothesis tests (false discovery rate [FDR] q value). Pair

enrichment pathways for each phenotype are classified. Gene sets with $NES \geq 1.0$, nominal P value ≤ 0.05 , and FDRq value ≤ 0.25 were identified as meaningful.

Protein-protein interaction (PPI) networks and screening for key genes in signaling pathways

PPI networks in meaningful signaling pathways were obtained through the online analysis website STRING (<https://string-db.org/>) and exported in.TSV format. The obtained source file was imported into the open source software platform Cytoscape (<https://cytoscape.org/>) for visual analysis, and the plug-in cytoHubba was used for hub gene analysis to screen for the key gene SMAD family member 3 (SMAD3).

Consensus clustering and immune cell infiltration analysis based on SMAD3, PPAR α , and NR1H4

Extraction and clustering of SMAD3, PPAR α , and NR1H4 expression was performed with the R package Consensus Cluster Plus (16). The sample was divided into two clusters.

CIBERSORT is a method of calculating cell composition based on an expression profile and can be used for almost any tissue. This algorithm was used to calculate the proportions of 22 immune cells in each BA patient. The sum of the 22 immune cell group fractions for each sample is 1 (17).

The degrees of infiltration of 28 immune cells were calculated based on the levels of gene expression in the 28 published immune cell genomes by applying the R Package GSVA Single Sample GSEA (ssGSEA) method. Data set GSE15235 is used for external validation.

Human samples

This study was reviewed and approved by the Institutional Review

Board of the Shanghai Children's Hospital. A total of 30 of BA, 28 of choledochus cyst (CC) patients' liver were used for verification. Liver samples of 10 BA and 10 CC patients were prepared as paraffin sections for immunohistochemistry, the remaining 38 were frozen and stored in liquid nitrogen for real-time PCR and western blot analyses.

Immunohistochemistry

Six paraffin sections approximately 4- μ m thick were excised from each tissue block and used for immunohistochemical

labeling with six antibodies purchased from Abcam (Cambridge, UK): recombinant anti-PPAR alpha [EPR21244], anti-solute carrier family 22 member 5 antibody, anti-CPT1A antibody, anti-CYP7A1 antibody, anti-ABCB4 antibody targeting the N-terminal, and human NR1H4 (FXR)/NR1H4 antibody.

Immunohistochemical staining was performed for PPAR α , NR1H4 (FXR), OCTN2, CPT1A, CYP7A1, and MDR3 (ABCB4) using the above-mentioned antibodies. Since PPAR α and NR1H4 (FXR) are expressed in the nucleus, immunohistochemical staining shows positive expression in the nuclei of hepatocytes. OCTN and MDR3 (ABCB4) were expressed on the cell membrane, and brownish-yellow staining of the hepatic cell membrane was considered as positive expression. Since CPT1A is expressed in the outer mitochondrial membrane and CYP7A1 is expressed in the endoplasmic reticulum and mitochondria, immunohistochemical staining revealed a positive brownish yellow color in the cytoplasm of the liver. All samples were processed with positive and negative controls.

Real-time PCR detection of NR1H4 (FXR), PPAR α , and SMAD3

Real-time PCR was performed to detect the expression of NR1H4 (FXR), PPAR α , and SMAD3 in liver tissues from both groups of patients. Ten frozen BA specimens were used as the experimental group, and fourteen with choledochal cysts were used as the control group. Liver tissue was minced and mixed with 0.5 ml of TRIzol to completely dissolve the samples, which were centrifuged at 12,000 g for 5 min at 4°C. The supernatant was collected and added to 250 μ l of chloroform, total RNA was extracted by the conventional TRIzol method, and the absorbance was measured in order to calculate the amounts of 1- μ g RNA samples. We prepared a well-mixed 20 μ l reverse transcription reaction system that was placed in a PCR machine for reverse transcription. We prepared a 10- μ l real-time fluorescent quantitative PCR reaction system. The primer sequences for the target genes and the control glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene are listed in [Table 1](#). Relative expression of the target gene was calculated by the 2- $\Delta\Delta$ Ct method. The amplification conditions were 95°C for 20 min, 95°C for 30 s, 58°C for 30 s, 40 cycles, 72°C for 40s.

Western blot detection of NR1H4 (FXR), PPAR α , and SMAD3

Western blotting was performed to detect the expression of NR1H4 (FXR), PPAR α , and SMAD3 in liver tissue. Approximately 100 mg of frozen tissue was thawed in 1 ml of protein lysis buffer, and total protein was extracted by an ultrasonic method. Protein concentrations were determined using the bicinchoninic acid method. Equal samples were loaded for gel electrophoresis, the

proteins were then transferred to membranes, which were blocked prior to adding the primary antibody for overnight incubation overnight at 4°C. The next day, the membranes were incubated with an appropriate secondary antibody for 1 hour at room temperature. Finally, the blot was incubated in a coloring solution, and the signal was developed after rinsing.

Statistical analysis

GraphPad Prism 9 (GraphPad Software, Inc, San Diego, CA, USA) was used to generate graphs, and SPSS 26.0 software (IBM Corp, Armonk, NY, USA) was used for data processing, measurement data (mean \pm standard deviation), and immunohistochemical semi-quantitative analysis in the BA group and common bile duct cyst group. The integrated optical density levels of the two groups were non-normally distributed continuous measurement data. Differences were compared using rank-sum tests, and $P < 0.05$ was considered statistically significant.

Results

Analysis of differentially expressed genes

The GSE46960 dataset was downloaded from the GEO database and processed with GEO2R software. It included samples of between BA liver tissue (64 patients) and control liver tissue (14 non-BA patients with intrahepatic cholestasis, 7 normal liver patients). Gene expression levels were analyzed, and genes with adjusted P-values (Padj) < 0.05 were considered as differentially expressed ([Figure 1A](#)). Histograms were drawn according to the expression levels of PPAR α , OCTN2, CPT1A, CYP7A1, MDR3, and NR1H4 (FXR). PPAR α , CYP7A1 and NR1H4 (FXR) were significantly differentially expressed between the two groups ([Figure 1B](#)).

Gene enrichment analysis

The gene set h.all.v7.4.symbols.gmt was used for GSEA to assess response pathways that may be involved in PPAR α and NR1H4

(FXR) signaling and BA development and progression. Gene expression data were divided into high and low expression groups according to PPAR α and NR1H4 (FXR) levels in GSE46960, and the results were validated in 47 BA patients in the GSE15235 dataset. Results that were not statistically significant in both datasets were excluded, and the same proportions of results from both groups were retained. For PPAR α and NR1H4 expression we used liver biopsy dataset GSE65359 (84 cases of hepatitis B), fetal and adult liver sample dataset GSE61276 (106 cases), and cholestasis gene expression excluding BA. Data were also selected from the GSE46960 (14 cases) and the GSE112790 liver cancer dataset (183 cases). The results showed that more BA-specific pathways were enriched in BA patients with low PPAR α and NR1H4 expression. When PPAR α expression is low, signaling is enhanced in the transforming growth factor- β (TGF β), p53, and phosphoinositide 3-kinase (PI3K)-AKT-mammalian target of rapamycin (mTOR) pathways (Figures 2A, B, E, F). Low NR1H4 expression is associated with inflammatory responses, interleukin (IL)6/STAT3 signaling, early estrogen response, IL2 STAT5 signaling, TGF β signaling, apoptosis, and angiogenesis (Figures 2C, D, G, H). TGF β signaling was significant in both groups. We found that the same signaling pathway was not screened in the PPAR and FXR high expression groups. The TGF β signaling pathway in the low expression group was significant in both groups (Table 2).

PPI networks and screening for key genes in signaling pathways

The online analysis website STRING was used to generate a network of interactions between TGF β pathway proteins and PPAR α , NR1H4, and other proteins. The resulting PPI network had a total of 57 nodes, 345 edges, and PPI enrichment $P < 1.0e-16$. Visual analysis was performed with Cytoscape (Figures 3A, B), and cytoHubba was used for hub gene analysis. The potential major hub gene was identified as SMAD3 (Figure 3C and Table 3). We then

screened all genes contributing to TGF β signaling in these two data sets of biliary atresia and confirmed that SMAD3 played an important role in both data sets (Figure 3D). We speculated that SMAD3 activated the TGF β pathway by interacting with PPAR α and NR1H4, thereby promoting BA-related biliary fibrosis.

Immune cell infiltration analysis

A correlation heat map was created for PPAR α and NR1H4, which are the major genes of the TGF β pathway (Figure 4A). Considering the important role of SMAD3 in the TGF β pathway and its close relationship with PPAR α and NR1H4, we included PPAR α , NR1H4 (FXR), and SMAD3 in the follow-up analysis. We performed consistent clustering of 64 BA samples based on PPAR α , NR1H4 (FXR), and SMAD3 expression matrices and split the samples into two clusters by median. The heat map showed low expression of SMAD3 and high expressions of PPAR α and NR1H4 (FXR) in cluster 1 ($n=36$), and high expression of SMAD3 and low expression of PPAR α and NR1H4 (FXR) in cluster 2 ($n=28$) (Figure 4B). Next we investigated the Spearman correlations between the three genes separately. We observed a positive correlation between PPAR α and NR1H4 ($R=0.48$, $P < 0.001$), and negative correlation between SMAD3 and PPAR α ($R=-0.41$, $P < 0.001$), as well as SMAD3 and NR1H4 ($R=-0.67$, $P < 0.001$). Consistent clustering was also carried out for the samples in the validation group GSE15235 according to the three genes, and similar heat maps were obtained. The 47 samples were divided into groups 1 cluster 1 ($n=27$) and cluster 2 ($n=20$) (Figure 4C).

Immune cell infiltration comparison

We performed CIBERSORT analysis and ssGSEA to better understand differences in immune function. CIBERSORT analysis showed that cluster 2 had high proportions of

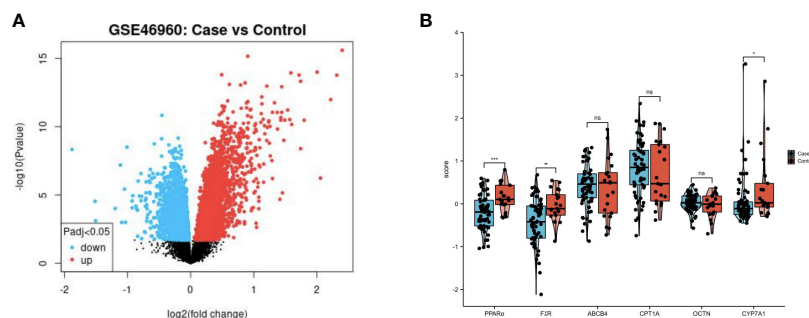

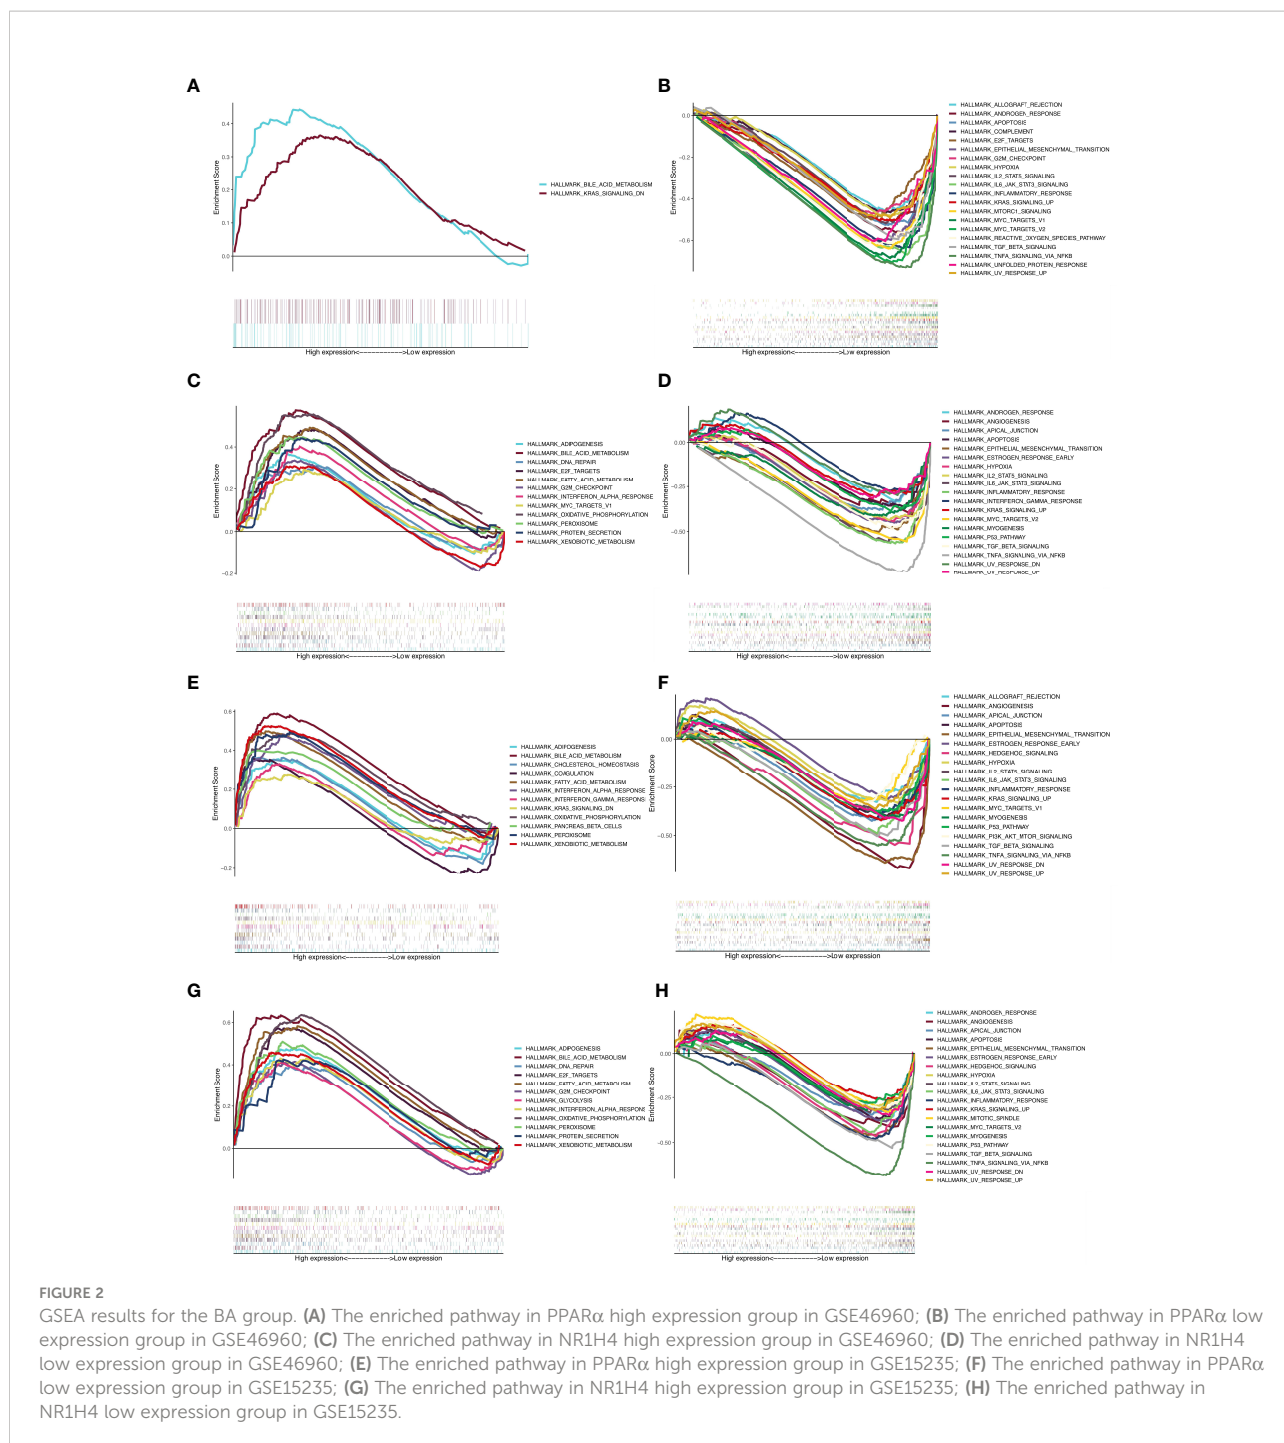

FIGURE 1

PPAR and FXR were downregulated in the liver of patient with BA. (A) Volcano plot of the GSE46960 dataset (BA patients: $n=64$, non-BA patients with intrahepatic cholestasis: $n=14$, and normal liver patients: $n=7$). PPAR α , NR1H4 (FXR) and SMAD3 expression in the BA and control groups

Samples from the control group showed complete hepatic lobule structure with hepatocellular cords lined up in an orderly manner. In the BA group, the extrahepatic bile duct was dilated and occluded to varying degrees, and the hepatic lobule and fibrous tissue around the bile duct were hyperplastic. Hepatocyte degeneration and necrosis were observed. The hepatic lobule structure and hepatic plate arrangement were disturbed, and intracellular cholestasis was noted (Figure 6A). The samples did not meet the requirements of normality testing ($P < 0.05$), so differences were compared with Mann-Whitney U tests. Quantitative comparisons of IHC results are shown in Figure 6B and Table 4.

closely associated with loss of CD56 (+), NK cells, and replacement expression of defective CD56 (-), CD16 (+), NK cells was observed with HIV infection. HCV infection impairs the overall NK cell response (23, 24). CD56 (-) was previously shown to be highly expressed in the liver of BA patients (25). Our study demonstrated higher CD56 (-)expression in cluster 2. Perhaps increased expression of CD56 (-) in BA and the subsequent immune response are also affected by several viral infections, causing a series of pathological changes. Monocyte

infiltration plays an important role in the development of angiogenesis in experimental hepatopulmonary syndrome after common bile duct ligation, with increased levels of monocytes in the lung and liver that are accompanied by a decrease in the number of circulating monocytes (26). Whether due to viral infection-induced edema or other mechanisms, BA is the first trigger mechanism for attracting neutrophils. Subsequent activation of Kupffer and bile duct cells leads to the recruitment of other inflammatory cells, and this sequence of

events is thought to be the result of pathological changes in BA rather than a causal mechanism (27). MCs migrate to the liver and are activated with cholestasis after liver injury in recent animal studies. Inhibition of MCs reduces the tube response and liver fibrosis, allowing the organ to heal in animal studies. The introduction of MC mimics cholestasis. Liver disorders, and MC-derived TGF β may be therapeutic targets for chronic cholestasis liver disease (28). Studies have shown that TGF β can effectively activate hepatic stellate cells, thereby promoting the production and secretion of extracellular matrix (ECM) proteins and causing liver fibrosis (29). In tumors, the TGF β signaling pathway has multiple roles including regulation of the tumor microenvironment and tumor cell behavior. Inhibiting TGF β signaling restores the ECM, regulates tumor vasculature, reverses epithelial-mesenchymal transition (EMT), damages cancer stem cells, and can enhance the response to chemotherapy (30, 31). Activation of the TGF β signaling pathway promotes hepatocyte EMT and fibrosis progression in animal models (32). *In vitro*, EMT is induced by TGF β in bile duct epithelial cells, causing BA fibrosis (33). The bile ducts innate immune response to dsRNA virus infection may induce EMT in bile duct epithelial cells by increasing tissue sensitivity to TGF β (34). Our experiments showed reduced expression of PPAR α and NR1H4 (FXR) mRNAs and proteins in BA liver tissue, while SMAD3 has the opposite trend. Upregulation of OCTN by PPAR α activation can be seen as a means of supplying sufficient carnitine to cells (9). At the same time, it can enhance CYP7A1 activity and increase the secretion of bile acids to reduce their levels in the liver (14, 35). Therefore, impaired activation of PPAR α signaling impairs carnitine utilization, reduces bile acid synthesis and secretion, affects NR1H4 (FXR) activation, and reduces the liver's ability to suppress inflammation. In this setting, there is likely to be apoptosis and fibrosis, while low expression of PPAR α and NR1H4/TGF β activates the SMAD3-mediated TGF β pathway, leading to the progression of BA and cirrhosis. Overall, cluster 2 with high SMAD3 expression and low PPAR α and NR1H4 expression had more identified mechanisms that promote disease progression. Presumably, interventions that enhance PPAR α and NR1H4 levels may reduce the immune response of BA patients, thereby improving their prognosis.

Conclusion

Our bioinformatics analysis and experimental validation results confirmed reduced PPAR α and NR1H4 (FXR) mRNA and protein levels in BA. PPAR α and NR1H4 can affect TGF β signaling through SMAD3. In addition, SMAD3, PPAR α and NR1H4 may affect the immune microenvironment of BA patients. The downregulation of PPAR α and NR1H4 (FXR) signaling pathway may be closely related to biliary atresia.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: <https://www.ncbi.nlm.nih.gov/genbank/>, GSE46960; <https://www.ncbi.nlm.nih.gov/genbank/>, GSE15235; <https://www.ncbi.nlm.nih.gov/genbank/>, GSE65359; <https://www.ncbi.nlm.nih.gov/genbank/>, GSE61276; <https://www.ncbi.nlm.nih.gov/genbank/>, GSE46960; <https://www.ncbi.nlm.nih.gov/genbank/>, GSE112790.

Ethics statement

Written informed consent was obtained from the minor(s)' legal guardian/next of kin for the publication of any potentially identifiable images or data included in this article.

Author contributions

YM and LL contributed equally to this work. YM, LL and ZG conceived the idea for the article and performed data analysis, data interpretation, and manuscript preparation. LL, FF, WW, and JM performed the data acquisition, ZL, GT, LZ, KT, and YW contributed to the critical review of the intellectual content of this manuscript.

Acknowledgments

We thank our colleagues and hospital for their help with this study during the COVID-19 pandemic. Special thanks to Professor Lv Zhibao for supporting our article.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

The handling editor declared a shared parent affiliation with the authors at the time of the review.

Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.
