Background: The role of second-line chemotherapy in advanced biliary cancers (ABCs) has only recently been established in phase III randomized trial and the optimal selection of patients most likely to benefit from it remains challenging.

Methods: A cohort of 98 ABC treated second-line chemotherapy was used as a developmental dataset to identify covariates independently associated with overall survival (OS). Kaplan–Meier analysis was used to investigate the association between variables and OS and those retaining statistical significance were combined in a multiplexed score.

Results: The following pretreatment variables were independently associated with OS: ECOG PS > 0, peritoneal disease, LDH > 430 UI/L, albumin <3.5 gr/dL, gamma-GT >100 UI/L, sodium <140 mEq/L, absolute lymphocyte count <1000/mm³, and PFS to first-line <6 months. Based on these results, a scoring system was developed that identified three subgroups with statistically different OS: low-risk (mOS 18 months), intermediate-risk (mOS 9.4 months) and high-risk (mOS 2.9 months) ($p < 0.001$). The prognostic model was both internally and externally validated in a multicentre cohort of 120 ABCs.

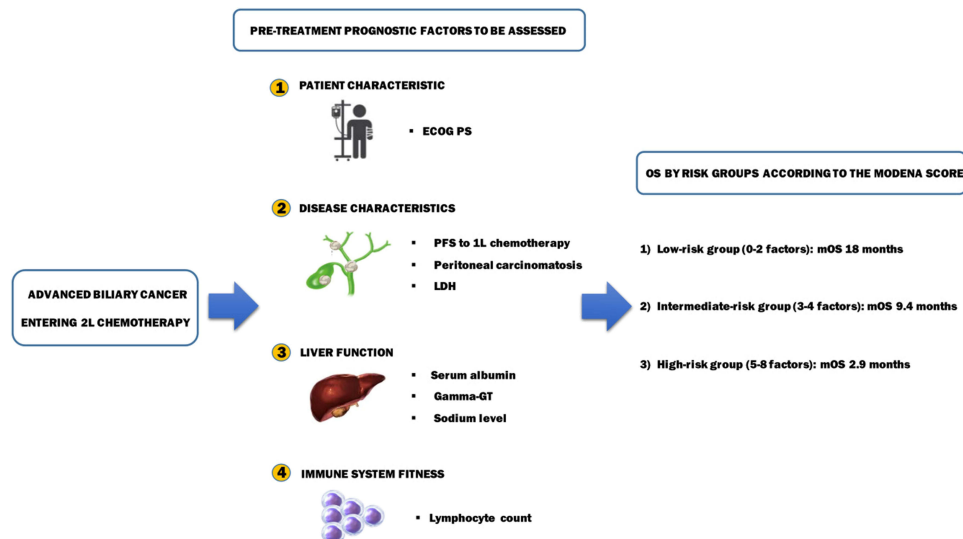

Conclusion: The Modena score is a multiplexed scoring system capable of accurately risk-stratified ABCs treated with second-line chemotherapy. Based on its reproducibility, usability and generalizability, it has the potential for assisting therapeutic decision-making in the clinic and risk-stratification in future trials.

Keywords: biliary tract cancer, chemotherapy, second-line, prognostic score, survival

Introduction

Biliary tract cancers (BTCs) are anatomically distinct and genetically heterogeneous tumor entities representing roughly 3% of gastrointestinal malignancies and the second most common primary liver cancer. Based on their anatomic location within the biliary tree, BTCs are commonly subdivided into intrahepatic (iCCA), perihilar (pCCA) and distal (dCCA) cholangiocarcinoma and gallbladder cancer (GBC).^{1,2} Despite being regarded as relatively rare tumors, their incidence is increasing steadily worldwide,³ mainly as a result of a rise in iCCA cases.^{4–6} Surgical resection followed by adjuvant capecitabine offers the only chance of cure in the 15–20% of patients diagnosed with potentially resectable disease. However, 68–86% of them still relapse and additional two-thirds present with unresectable advanced-stage disease at

Graphical Abstract

diagnosis.⁷ Palliative-intent chemotherapy in the form of cisplatin and gemcitabine combination is the standard regimen for recurrent, locally advanced and metastatic BTCs resulting in median overall survival (mOS) around 12 months.⁸

For patients failing first-line, until recently only a poor level of evidence (level C) was available to support the use of second-line chemotherapy so that its benefit has been largely debated in recent years.⁹ A systematic review of the literature pooling together data from 25 prospective uncontrolled and retrospective studies involving 761 patients suggested a benefit in selected patients with good performance status (PS).¹⁰ However, the interpretation of these results has been challenged by potential inherent biases and heterogeneity across studies. In parallel, active symptom control is considered an alternative standard of care endorsed by international guidelines for advanced biliary cancer (ABC) patients who progress following first-line chemotherapy.⁹ Nonetheless, 20–40% of patients are offered salvage chemotherapy in clinical practice, based on a case-by-case discussion within the multidisciplinary tumor board.^{11–16} Finally, the results of the first prospective randomized phase III trial (ABC-06) in this setting have been presented showing a reduced risk of death for patients treated with mFOLFOX6 regimen compared to active symptom control alone (HR 0.69; $p = 0.031$).¹⁷

Notably, the balance between the risks and benefits of a treatment resulting in a 1-month absolute mOS advantage and increased toxicity needs to be carefully evaluated. To this end, there exists an urgent need for factors guiding treatment selection to identify patients more likely to benefit from second-line chemotherapy. In this study, we aimed at developing a user-friendly and robust prognostic tool to assist in the decision-making process of ABC progressing on or after upfront chemotherapy.

Patients and Methods

Patient Selection

Patients with cyto-histologically proven unresectable locally advanced or metastatic BTCs treated with second-line chemotherapy were retrospectively identified from the Modena Cancer Centre Biliary Tract Cancer Database (training cohort; TC).

The validation cohort (VC) was made up of ABC patients undergoing second-line treatment at the following Italian Centres: Milano, Napoli, Cefalu' (Palermo), Trento and Cremona.

Patients with mixed hepatocellular-cholangiocellular carcinoma and ampullary carcinoma, as well as those with signs and/or symptoms suggestive of infectious disease within two weeks of starting treatment, were deemed not eligible. Moreover, treatment with immunotherapy, targeted therapy and investigational drug, together with liver-directed loco-regional procedures were not allowed.

Baseline clinical and laboratory data were retrieved through electronic medical records review and the following baseline variables were collected and analyzed before the commencement of second-line chemotherapy: age, gender, ECOG PS, primary tumor site, disease status, first-line regimen, progression-free survival (PFS) to first-line. Still, haematological and biochemical parameters including white blood cell count (cell/ μ L), haemoglobin (gr/dl), platelet count (cell/ μ L), lymphocyte count (cell/ μ L), neutrophil count (cell/ μ L), total bilirubin (mg/dL), alkaline phosphatase (ALP; IU/L), lactate dehydrogenase (LDH U/L), alanine aminotransferase (ALT; IU/L), aspartate aminotransferase (AST; IU/L), gamma-GT (UI/L), albumin (g/dL), sodium (mEq/L), carbohydrate antigen 19-9 (CA 19-9) (U/mL), and carcinoembryonic antigen (CEA) (ng/mL).

The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki. Data accessed complying with relevant data protection and privacy regulations were collected under the protocol 183-2019/OSS/AOUMO. The protocol was reviewed and approved by the Area Vasta Emilia Nord Ethics committee, which serves the University Hospital of Modena and the surrounding geographical area.

Statistical Analysis

The primary endpoint was OS calculated from the date of the first cycle of second-line chemotherapy to the date of death for any cause or last follow-up visit. In descriptive statistics, continuous variables were reported as the median and 25–95 percentile, while categorical variables were reported as absolute and percentage frequencies. Laboratory variables initially recorded as continuous parameters were later dichotomized according to the usual clinical thresholds reported in the literature or according to their upper 75 percentile, chosen as worst status. The OS was calculated using Kaplan–Meier estimators.¹⁸ Statistical comparisons between the curves were performed with the Log rank test and the effects were estimated using the Cox proportional hazard (PH) regression analysis, with a confidence interval at 95% (95% CI).¹⁹ The proportionality of hazard was checked graphically using scaled Schoenfeld residuals.²⁰ The prognostic performance of each variable on OS was first evaluated through PH univariate model, selecting covariates with *p*-value <0.20. The final model was developed step by step in multiple Cox PH regression using the likelihood ratio test. Furthermore, the over-optimism and calibration of the model were computed over 250 bootstrap replications employing the Harrell's methods.²¹

The specificity and sensitivity of the prognostic model were evaluated with the ROC-AUC curves according to Heagerty et al.²²

Both internal and external validations were performed, and measures of model performance were reported to assess the reliability and generalizability of the model. Discrimination is presented graphically by a Kaplan–Meier plot of survival for patients in different risk groups, and the c-Harrell index was used as a measure of discriminant power of the model. Calibration was evaluated through reporting at a fixed time point, a comparison of predicted percentage survival in risk groups with actual survival percentages.²³

The statistical analyses were performed using Stata version 14.0 or later (StataCorp. LLC, College Station, TX, USA).

Results

Training Cohort

Between 1st January 2008 and 31st December 2020, a total of 98 ABC patients (39%) fulfilling the aforementioned criteria were identified and included in the analysis. The median age of patients was 63 years (range 29–82 years), with a slight prevalence of females (53%). The most common primary tumor site was iCCA (62%), followed by eCCA (22%) and GBC (16%). All the patients had metastatic disease.

Overall, the vast majority of patients (72%) received platinum/gemcitabine doublet chemotherapy as a first-line treatment, resulting in a disease control rate of 69%. The mPFS to first-line was 5 months (range 1–38), with 61% of patients progressing within 6 months from treatment commencement.

Upon disease progression, fluoropyrimidine-based chemotherapy was the preferred second-line choice in the form of mFOLFIRI (26%), mFOLFOX6 (20%) and fluoropyrimidine monotherapy (19%), respectively. Regarding second-line antitumor activity, the disease control rate was achieved in 39% of patients, yielding a 7% of objective responses. Other baseline clinicopathologic and laboratory characteristics are summarized in Table 1.

As of data cut-off, a total of 94 deaths had occurred. The median OS in the whole patient population was 7.2 months (95% CI; 7–14 months), while the mPFS was 3.5 months; the 1-year OS and 2-year OS were 28% (95% CI; 20–37) and 7% (95% CI; 3–14), respectively.

Development of the Prognostic Model, Scoring System and Risk Groups

Globally, among all the covariates tested in the univariate analysis for OS in the VC, the following were associated with shorter OS: male gender ($p = 0.032$), ECOG PS > 0 ($p < 0.001$), peritoneal involvement ($p < 0.001$), LDH > 430 ($p = 0.001$), albumin < 3.5 gr/dl ($p < 0.001$), absolute lymphocyte count $< 1000/\text{mmc}$ ($p = 0.001$), absolute monocyte count $> 630/\text{mmc}$ ($p = 0.002$), absolute neutrophil count $> 8000/\text{mmc}$ ($p < 0.001$), lymphocyte–monocyte ratio < 2.1 ($p = 0.001$), neutrophil–lymphocyte ratio > 3 ($p < 0.001$), sodium < 140 mEq/L ($p < 0.001$), gamma-G > 100 UI/L ($p = 0.003$), GOT > 40 UI/L ($p = 0.034$), GPT > 45 UI/L ($p = 0.005$), CA $19.9 > 700$ UI/L ($p < 0.001$), PFS to first-line < 6 months ($p < 0.001$). At the multivariate analysis for OS, the following covariates retained statistical significance as poor prognostic factors: ECOG PS > 0 ($p = 0.002$), peritoneal involvement ($p < 0.001$), LDH > 430 UI/L ($p < 0.001$), albumin < 3.5 gr/dL ($p = 0.001$), gamma-GT > 100 UI/L ($p = 0.001$), sodium < 140 mEq/L ($p = 0.010$), absolute lymphocyte count $< 1000/\text{mmc}$ ($p = 0.030$), and PFS to first-line < 6 months ($p = 0.025$) (Table 2).

Based on these eight variables, a prognostic model was developed to predict OS, and a prognostic score was derived from the model as a sum of the variables, assuming each of these weighted equally to 1. This scoring system was named after the institution, which serves as the TC (ie Modena Score). Then, three risk groups were identified as follows: a low-risk group (0–2 negative prognostic factors), an intermediate-risk group (3–4 negative prognostic factors) and a high-risk group (5–8 negative prognostic factors) (Table 3). Globally, the patients were evenly distributed across these risk groups, with 27 (27%) patients categorized as low-risk, 35 (36%) patients as intermediate-risk and 36 (37%) as high-risk. The survival was significantly different between groups ($p < 0.001$): the mOS for low-, intermediate-, high-risk group was 18 months (95% CI, 14.7–21.2 months), 9.4 months (95% CI, 7.9–11.0 months), and 2.9 months (95% CI, 2.4–3.5 months), respectively. Survival curves according to risk-group stratification are depicted in Figure 1. With regard to the reproducibility of the model, the internal validation showed a shrinkage (overfitting) of 0.128 (250 bootstraps) and c-Harrell index of 0.847.

The ROC-AUC for the prognostic model in the training sample at 12 months of follow-up was 0.886, with a specificity of 0.986 and sensitivity of 0.664 at the median value of the linear prediction. The ROC-AUC associated with median linear prediction in the test sample was 0.820 (specificity 0.886 and sensitivity 0.688), with an AUC ratio between training/validation sample of 0.926.

With the aim of providing a simpler and user-friendly pictorial representation of our model, a prognostic nomogram including selected covariates has been constructed (Figure 2).

External Validation Cohort

The VC included a total of 120 patients (35%), enrolled from 1st January 2006 to the 31st December 2018 at five Italian Cancer Centres. Baseline demographic and clinicopathologic characteristics were well balanced compared to the TC. The median age was 65 years old, 61 were male (51%). Overall, 64 (54%) patients had iCCA, 35 (29%) GBC and 21 (23%) eCCA. A total of 78 (65%) patients received multiagent chemotherapy, among which mFOLFIRI (35%) was the most commonly adopted regimen, followed by mFOLFOX (29%). The median OS was 7.5 months (95% CI; 5.9–8.6 months) and 1-year OS was 17.5% (95% CI 10–24). Regarding the prognostic variables of interest: 80 (67%) patients had ECOG PS > 0 , 30 (25%) had peritoneum involvement, 56 (47%) LDH > 430 U/L, 66 (55%) had albumin < 3.5 g/dL, 30 (25%)

had gamma-GT >100 UI/L, 50 (42%) had progression-free survival to first-line <6 months, 42 (35%) Na⁺ <140 mEq/L, 71 (59%) absolute lymphocyte count <1000/uL. In the VC, 25 (20%), 47 (40%) and 48 (40%) patients were assigned to the low-, intermediate- and high-risk group, according to the presence of 0–2, 3–4 and 5–8 risk factors, respectively. The score was able to identify prognostic classes with different median OS: 12.8 months (7.4–11.0), 6.4 months (5.2–8.3) and 2.5 months (1.8–2.7), in the low-, intermediate- and high-risk groups, respectively ($p < 0.001$) (Figure 3). The performance of the prognostic model in the VC was adequate, in terms of both discrimination (c-Harrell index 0.712; D-Royston 1.467) and prediction accuracy (calibration slope = 0.65).

Table 2 Multiple Cox Proportional Hazard Regression in the Training Cohort (n = 98)

Factor	HR (95% CI)	p-value
ECOG PS >0	2.33 (1.38–3.95)	0.002
Peritoneal involvement	2.93 (1.70–5.07)	<0.001
LDH >430 UI/L	3.30 (1.92–5.67)	<0.001
Albumin <3.5 g/dL	3.14 (1.55–6.24)	0.001
Gamma-GT >100 UI/L	2.44 (1.47–4.07)	0.001
PFS to 1st line <6 months	1.75 (1.07–2.85)	0.025
Na⁺ <140 mEq/L	2.93 (1.29–6.63)	0.010
ALC < 1000 /uL	1.94 (1.07–3.53)	0.030

Table 3 Risk-Group Assignment Based on the Prognostic Score in the Training Cohort (n = 98)

Risk Group	N (%)	1-Year OS% (95% CI)	HR (95% CI)	p-value	Median OS (Months)
Low (0/2)	27 (27)	69 (48–83)	1.00		18.0 (14.7–21.2)
Intermediate (3–4)	35 (36)	26 (13–41)	3.78 (2.09–6.84)	<0.001	9.4 (7.9–11.0)
High (5/8)	36 (37)	NA	32.2 (27.0–38.1)	<0.001	2.9 (2.4–3.5)
		High vs Intermediate	16.5 (7.55–25.9)	<0.001	

Notes: Score: PS, peritoneum, LDH, albumin, ALC, Na⁺, g-GT, time to 1st progression with weight = 1. Score from 0 to 8, stratified in three groups of risk.

Discussion

In the present study, we developed a prognostic model and a scoring system based on eight variables (ie PFS to first-line, ECOG PS, peritoneal carcinomatosis, LDH, albumin, sodium, lymphocyte count, gamma-GT) showing an accurate performance in risk-stratified ABC patients treated with second-line chemotherapy into three statistically different prognostic subgroups. Interestingly, we validated our findings in an external independent cohort of 120 patients enrolled across five Italian Cancer Centres.

Only recently, the value of second-line chemotherapy for ABC has been established in a randomized fashion.¹⁷ In the phase III ABC-06 trial, 162 patients progressing on or after cisplatin/gemcitabine combination were randomly allocated (81 in each arm) to either active symptom control plus mFOLFOX6 or active symptom control alone. The administration of salvage chemotherapy resulted in improved survival, with mOS and 1-year OS of 6.2 months (vs 5.3 months) and 25.9% (vs 11.4%), respectively. As expected, grade 3–4 adverse events, particularly fatigue and neutropenia, were more commonly reported in the experimental arm. On the other hand, new horizons of precision medicine are heading to the targeting of actionable drivers, such as FGFR fusion rearrangements and IDH1/IDH2 mutations with promising results in clinical trials.^{23–27}

Although statistically significant, the relative benefit provided by second-line chemotherapy in ABC is clinically marginal, and it has to be balanced against increased toxicity and impaired quality of life. Moreover, only 20% to 40% of patients remain candidates to second-line because of their rapidly worsening PS and the occurrence of biliary

Number at risk

High-risk group	36	2	0	0	0	0	0
Intermediate-risk group	35	27	8	4	1	0	0
Low-risk group	27	27	18	9	7	1	1

Figure 1 Overall survival by risk groups in the training cohort (n=98). Kaplan–Meier curves of overall survival (OS) according to the Modena score in the training cohort. The prognostic score assigned patients to three risk groups with statistically different OS: low-risk (n=27; mOS 18 months), intermediate-risk (n=35; mOS 9.4 months) and high-risk (n=27; mOS 2.9 months) (p<0.001).

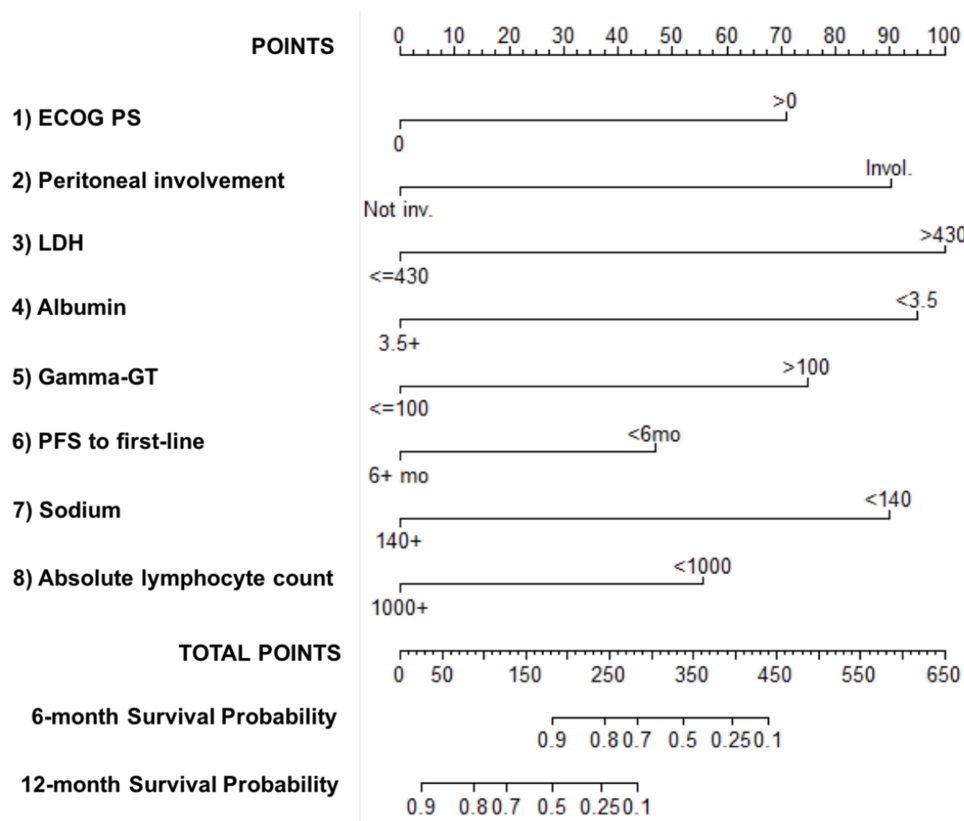

Figure 2 Nomogram for overall survival of biliary cancers treated with second-line chemotherapy. Using and interpreting the nomogram. Each variable incorporated in the Modena score has been listed separately together with the corresponding number of points reflecting its magnitude. For each variable, draw an upward vertical line to the “Points” bar to calculate points, then sum the points for each variable and locate this sum on the “Total Points” axis. Draw a downward vertical line from the “Total Points” line to calculate 6-month and 12-month overall survival probability.

Number at risk

High-risk group	55	0	0	0	0
Intermediate-risk group	43	15	3	0	0
Low-risk group	22	18	11	3	0

Figure 3 Overall survival by risk groups in the validation cohort (n=120). Kaplan–Meier curves of overall survival (OS) according to the Modena score in the validation cohort. The prognostic score assigned patients to three risk groups with statistically different OS: low-risk (n=22; mOS 12.8 months), intermediate-risk (n=43; mOS 6.4 months) and high-risk (n=55; mOS 2.5 months) (p<0.001).

tract-related complications.^{28–30} Nonetheless, no specific molecular signatures or biomarkers have been incorporated in the decision-making process in ABC. Thus, the search for a clinical tool enabling a more accurate prediction of patients' prognosis to maximize the benefit/risk ratio of second-line chemotherapy is an area of active investigation.

Past studies have independently reported several factors to be correlated with survival in this setting, among which are ECOG PS, prior surgery on the primary tumor, disease status, PFS to first-line, and CA19.9.^{31–36} However, individually each factor has limited accuracy in prognostication and is insufficient to reflect the complex biological impact of this disease. More recently, four independent prognostic factors (ECOG PS, the reason for L1 discontinuation, peritoneal carcinomatosis and prior surgery) were combined in a clinical prognostic model developed from a large French retrospective analysis and validated in three multinational patient cohorts (n = 392).³⁷ However, currently, there is neither prospectively validated nor widely accepted clinical prediction model to be routinely applied to the decision-making of ABC undergoing second-line chemotherapy.

The treatment outcomes of our study are comparable to previously published experiences in this setting, showing a mPFS around 3 months and mOS in the range of 6.3–7.2 months. Again, the pattern of care is characterized by a slight prevalence of irinotecan-based doublets as consistently reported across Europe, except in the UK, where oxaliplatin-based regimens are more common following cisplatin/gemcitabine first-line.

Of note, we were able to confirm the prognostic value of established clinical variables in the multivariate analysis, including ECOG PS, peritoneal carcinomatosis and PFS to the first-line. More interestingly, we provided a comprehensive characterization of potential prognosticators, including in our analysis additional biological factors compared to previous studies. To this end, we showed for the first time that LDH, sodium, lymphocyte count, and gamma-GT were independent predictors of outcome in this setting. In particular, the inclusion of liver function parameters represents an added value in light of the sizeable proportion of iCCA (>50%) recruited in the study, among whom chronic liver disease is a highly prevalent underlying condition.

A multiplexed score incorporating patient (ECOG PS), disease (PFS to first-line, peritoneal carcinomatosis, LDH), organ function (albumin, sodium, gamma-GT) and immune system (lymphocyte count) determinants may better account for the heterogeneity and complexity of this disease. Hence, offering a more accurate tool for prognosis prediction for both trial design and daily practice. When applied to the clinical scenario, the Modena score may identify a subgroup of ABC portending a particularly poor prognosis (OS < 3 months), for whom best supportive care alone seems advisable. On the other hand, the intermediate- and even more the low-risk group seem to be the best candidates for a treatment strategy with multiple lines in light of their favourable behaviour. The retrospective design of our study along with its relatively small sample size are limitations to be acknowledged that may have precluded us from the proper assessment of additional variables of potential interest as well from the presence of confounders. Still, prospective validation of our findings in larger patient populations is required in the future.

Conclusions

In conclusion, we provided evidence of a clinical prognostic model and score constructed in a rigorous methodological framework for ABC amenable to second-line chemotherapy. This model takes into account several prognostic determinants and bears the potential for improving the accuracy of currently available prediction tools. It is proved to be reproducible, easily usable, and generalizable. We, therefore, believe that it could become a useful tool for guiding therapeutic decisions in clinical practice and risk-stratification in future clinical trials.

Cancer Management and Research

Dovepress

Publish your work in this journal

Cancer Management and Research is an international, peer-reviewed open access journal focusing on cancer research and the optimal use of preventative and integrated treatment interventions to achieve improved outcomes, enhanced survival and quality of life for the cancer patient. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/cancer-management-and-research-journal>
