Abstract: Glioblastoma multiforme (GBM) is the most common and most aggressive malignant primary brain tumor in humans. Current GBM treatment includes surgery, radiation therapy, and chemotherapy, sometimes supplemented with novel therapies. Despite recent advances, survival of GBM patients remains poor. Major challenges in GBM treatment are drug delivery across the blood–brain barrier, restriction of damage to healthy brain tissues, and limitation of resistance to therapies. This article reviews recent advances in the application of magnetic nanoparticles (MNPs), gold nanorods (GNRs), and carbon nanotubes (CNTs) for hyperthermia ablation of GBM. First, the article introduces GBM, its current treatment, and hyperthermia as a potential modality for the management of GBM. Second, it introduces MNPs, GNRs, and CNTs as inorganic agents to induce hyperthermia in GBM. Third, it discusses different methodologies for synthesis of each inorganic agent. Finally, it reviews *in vitro* and *in vivo* studies in which MNPs, GNRs, and CNTs have been applied for hyperthermia ablation and drug delivery in GBM.

Keywords: hyperthermia, targeted drug delivery, SPIONs, gold nanorods, carbon nanotubes

Introduction

Glioblastoma multiforme

Gliomas are heterogeneous central nervous system tumors.¹ Glioblastoma multiforme (GBM) is the most frequent and malignant type of glioma, and despite advances in diagnosis and treatment of GBM, median survival of GBM patients remains less than 15 months.² There are at least two factors that make GBM treatment extremely difficult. First, the brain has limited capacity to repair itself. Second, GBM is highly invasive and resistant to therapies.³

Conventional GBM therapies consist of surgery, radiotherapy (RT), and chemotherapy. Objectives of surgery range from merely confirmation of the diagnosis or alleviation of symptoms due to mass effects to aggressive attempts to improve quality of life and prolong survival of the patient.³ RT is one of the oldest and most common treatment options for GBM patients. It is based on generation of electrons and free radicals by ionizing radiation to damage deoxyribonucleic acid (DNA). Early clinical trials revealed a modest, yet undeniable efficacy of RT in treating GBM. However, there are several limitations of RT including risk of necrosis, permanent neuronal damage, and radio resistance of certain tumor types (Figure 1).⁴

Temozolomide has been the mainline chemotherapy drug for GBM treatment for over 10 years.⁵ Temozolomide, an oral alkylating agent, is a second-generation imidazotetrazine derivative, which exhibits cytotoxic effects by methylation of specific DNA sites.⁵

Bevacizumab is often used as adjuvant therapy for GBM treatment. It is a humanized monoclonal antibody against vascular endothelial growth factor that act as angiogenesis inhibitor.⁶ Side effects of chemotherapy are often severe, including nerve damage, nausea, hair loss, and infertility (Figure 1). Chemotherapy in combination with other therapies, especially RT, provides the most effective treatment strategy for GBM at the moment.⁵ For instance, a Phase III study conducted by the European Organization for Research and Treatment of Cancer and the National Cancer Institute of Canada reported that combined therapy of RT and temozolomide increased median survival time significantly when compared with RT alone.⁷ The 5-year overall survival rate was 9.8% for the combination therapy group versus 1.9% for the RT alone group, with a median follow-up of 61 months. This and other studies are paving the way toward new treatment combinations.

Hyperthermia

Hyperthermia is a fairly new concept that finds its application in the treatment of different types of cancers and is based on generation of heat at the tumor site. This results in changes in the physiology of diseased cells, finally leading to apoptosis.⁸

Hyperthermia treatment mechanisms involve intracellular heat stress in the temperature range of 41°C–46°C, resulting in activation and/or initiation of many intracellular and extracellular degradation mechanisms. The intracellular and extracellular effects of hyperthermia include protein misfolding and aggregation, alteration in signal transduction, induction of apoptosis, changes in potential of hydrogen (pH), and reduced perfusion and oxygenation of the tumor.⁸

The effectiveness of hyperthermia treatment greatly depends on the temperature profile at the targeted tumor site, duration of exposure, and characteristics of cancer cells.^{9,10} Traditionally, hyperthermia treatment was performed using external devices to transfer thermal energy to cancerous tissues, either by irradiation with light or electromagnetic waves. Conventional techniques for induction of hyperthermia are ultrasound, microwaves, infrared irradiation, and tubes with hot water. However, each of these methods suffers from limitations (Table 1),¹⁰ including low penetration of heat in the tumor; excessive heating of healthy tissue; thermal under-dosage in the target region; and dissipation of heat by the blood, which is especially a problem in well-vascularized tumors.^{10,11}

To overcome these limitations, magnetic materials were first proposed for hyperthermia treatment of cancer in 1957.¹² Many approaches have evolved since then to develop a new therapeutic system called magnetic hyperthermia therapy (MHT). MHT is based on generation of heat by magnetic nanoparticles (MNPs) when exposed to alternating magnetic fields. When MNPs are injected in the tumor and an alternating magnetic field is applied, the tumor temperature rises and results in thermal ablation of tumor cells.¹³ MHT encompasses many salient features including externally-stimulated intracellular heating, delivery through multiple routes, potential to cross the blood–brain barrier, and antitumoral immunity.^{13,14}

Nanoparticle-based hyperthermia MNPs

In the last decade, several types of iron oxides have been explored to synthesize MNPs, including magnetite (Fe₃O₄), hematite (α-Fe₂O₃), and maghemite (γ-Fe₂O₃ and β-Fe₂O₃).¹⁵ MNPs are the most frequently investigated nanoparticles for

Table 1 Types of hyperthermia therapy in cancer treatment

Hyperthermia type	Delivery mode	Advantages	Disadvantages
Thermal conduction	Heated water	None	Heat penetration up to 3–5 mm
Radiation hyperthermia	Lower frequency waves	Moderate penetration	Hyperthermia of healthy tissues
Magnetic induction hyperthermia	Magnetic field	Deep penetration	Toroidal heating pattern and low magnetic energy absorption
Ultrasound power deposition	Pressure waves	Optimization of penetration by modulating frequency	Limited application in anatomic body locations

biomedical applications because of their biocompatibility.¹⁵ Among MNPs, superparamagnetic iron oxide nanoparticles (SPIONs) are the nanoparticles of choice due to their unique optical and magnetic properties, such as high paramagnetism, coercivity, magnetic susceptibility, and low Curie temperature.¹⁶

Coercivity and Curie temperature are two important properties for nanoparticles. Coercivity of ferromagnetic material is a measure of intensity of the applied magnetic field that is required to reduce the magnetization of a material to zero.¹⁷ Thus, coercivity measures the resistance of ferromagnetic material to demagnetize. Curie temperature is the temperature where the permanent magnetism of material changes to induced magnetism. When the Curie temperature is known, overheating of tumor tissue can be avoided, and thus side effects on healthy tissue can be limited.¹⁸ Preliminary studies have suggested that MHT has potential to be applied for treatment of GBM. In fact, SPIONs have shown uniform intratumoral distribution and controlled heating of GBM without major side effects.¹⁹

For the application of MNPs in MHT, their physical and chemical properties need to be optimized, which is a technological challenge. The next section discusses strategies for synthesis of different types of MNPs.

Methods for the synthesis of MNPs

Methods that are most commonly used for MNP synthesis are chemical coprecipitation, thermal decomposition, and microemulsion (Figure 2). Other less commonly used methods include hydrothermal synthesis, sonochemical synthesis, and electrochemical synthesis.²⁰ Control of size, stability, biocompatibility, and monodispersity of nanoparticles are some of the most important factors to consider before selecting a synthesis route.²⁰ The three most commonly used methods to synthesize MNPs are discussed here.

Chemical coprecipitation

In this method, hydrolysis of a mixture of Fe²⁺ and Fe³⁺ ions in 2:1 molar ratio is carried out under inert atmosphere. Ferrous and ferric ions are mixed in a 2:1 molar ratio at pH 8–14. Magnetite precipitates after being formed according to the following reaction:

Structural characteristics, such as size, dispersion, and morphology, of MNPs mainly depend on the type of salts

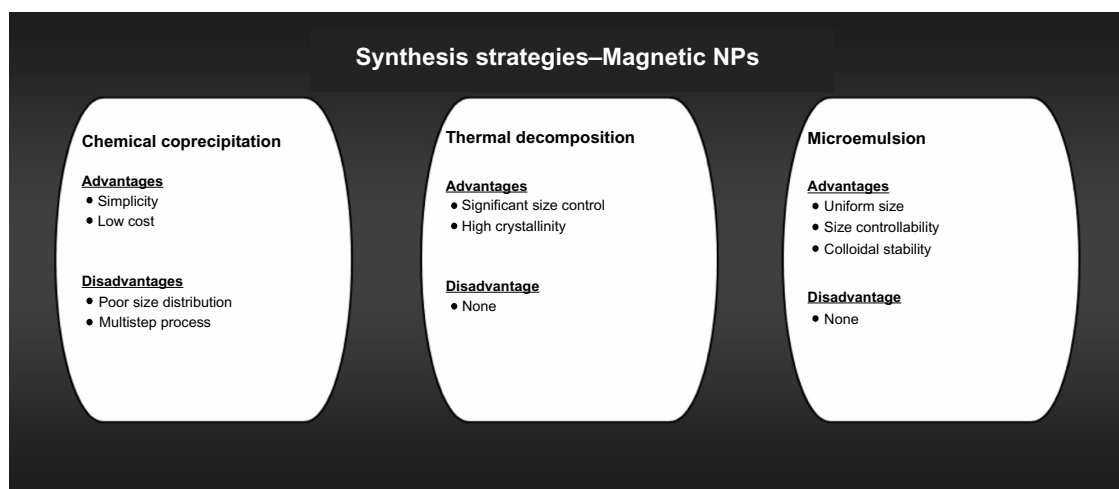

Figure 2 Methods for the synthesis of magnetic nanoparticles.
Abbreviation: NPs, nanoparticles.

used, the ratio of ferric and ferrous ions, and the reaction temperature.²¹ Coprecipitation synthesis involves two major steps: first, formation of nuclei and second, growth of nuclei. The advantage of coprecipitation synthesis is the possibility to synthesize industrial quantities of nanoparticles. Large size distribution is the most common problem associated with coprecipitation. To overcome this problem reaction conditions are varied, such as pH, temperature, nature and origin of salts, and the $\text{Fe}^{3+}/\text{Fe}^{2+}$ ratio.^{21,22}

Thermal decomposition

Thermal decomposition is carried out in an organic solution and results in formation of monodispersed iron oxide nanoparticles, with significant size control and crystallinity. Thermal decomposition involves decomposition of iron complexes in the presence of surfactants and organic solvents at high temperatures.²³

Sun and Zhang²⁴ prepared SPIONs using thermal decomposition. Reactions of iron (III) acetylacetonate were performed at a high temperature (265°C) in the presence of phenyl ether, alcohol, oleic acid, and oleylamine to form SPIONs with a diameter of 4 nm. Hyeon et al²⁵ synthesized SPIONs with a diameter of 7–25 nm by thermal decomposition. In their study, nanoparticles were synthesized as iron oleate complexes from iron pentacarbonyl by decomposition in the presence of octyl ether and oleic acid at 100°C. Park et al²⁶ used iron salt (iron chloride [$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$]) instead of toxic ferrous metallic compounds as precursor to form an iron-oleic complex. Iron-oleic complexes yielded monodispersions of iron oxide crystals when mixed with sodium oleate in the presence of 1-octadecene and aged for 30 minutes.

Microemulsion

Iron oxide nanoparticles generated in the presence of microemulsions yield nanoparticles of uniform size and colloidal stability. Inouye et al were the first to synthesize MNPs in microemulsion by oxidation of Fe^{2+} salts, and the size of MNPs was controlled by varying temperature and surfactant concentration.²⁷ Micelles have been immensely useful in synthesizing monodispersed, size-controlled nanoparticles. Lee et al used reverse micelles (micelles with head groups in the center and tails at the periphery) for the synthesis of SPIONs.²⁸ This method to generate monodispersed SPIONs is efficient, inexpensive, and large-scale, and it involves synthesis of MNPs at high temperatures using iron salts, surfactant, and solvents in varying concentrations or proportions.²⁸

Methods for the surface modification of MNPs

MNPs are susceptible to corrosion. The most common form of corrosion that occurs in MNPs is oxidation, which leads to loss of magnetism and dispersibility of nanoparticles, thus affecting their ability to induce hyperthermia. Therefore it is necessary to protect MNPs from oxidation. Methods that have been explored to protect MNPs against oxidation include surface modification by surface passivation, surfactant and polymer coating, and metal, silica, and carbon coating. A detailed review on this topic has already been published. A brief overview of methods for surface modification of MNPs is presented below.

Surface passivation by mild oxidation

Surface passivation is the protection of any material from external environmental factors, and surface passivation by mild oxidation has been used for protecting MNPs.^{29,30} Peng et al used plasma gas condensation to oxidize cobalt nanoparticles in gas phase.²⁹ Bönnemann et al used controlled air atmosphere to oxidize cobalt nanoparticles, and this resulted in the formation of an outer layer of cobalt oxide on the nanoparticle and protected it from further oxidation.³⁰

Surfactant and polymer coating

MNPs synthesized through coprecipitation carry negatively charged surfaces, causing them to agglomerate. Surfactants and polymers have been peptized, chemically anchored, or physically adsorbed on MNPs to form stable colloids.^{31–33} These stable colloids create repulsive forces to balance the magnetic and the van der Waals attractive forces acting on the nanoparticles, thus preventing nanoparticles from agglomeration. Polymers that have been used for the formation of stable colloids are poly(pyrrole), poly(aniline), poly(alkyl cyanoacrylates), poly(methylidene malonate), poly(lactic acid), poly(glycolic acid), and poly(ϵ -caprolactone).^{34–37}

Metal, silica, and carbon coating

Precious metals deposited onto MNPs protect the magnetic nanoparticle core from oxidation. Of all precious metals, gold is the metal of choice for coating MNPs due to its low reactivity. However, direct coating of gold onto MNPs is difficult because of the dissimilar nature of the two surfaces.^{38,39} Despite this complication, many researchers have been able to coat MNPs with gold by using new techniques. Ban et al synthesized gold-coated iron nanoparticles using a partial replacement reaction in a polar aprotic solvent,⁴⁰ Liu et al synthesized gold-coated iron nanoparticles using a

reverse microemulsion method,⁴¹ and Zhang et al synthesized iron (core) gold (shell) nanoparticles using a combination of wet chemistry and laser irradiation.⁴²

Gold nanorods

Gold nanorods (GNRs) exhibit optical properties that depend on size and aspect ratio. Surface plasmon resonance is the most important property of GNRs. It is a result of interaction between electrons in a conduction band of gold atoms and electric field components of incident electromagnetic radiation.⁴³ As a result of surface plasmon resonance, GNRs emit heat upon irradiation with an infrared laser. This property was used in numerous studies to develop photodynamic therapy for GBM treatment.⁴⁴ The most efficient strategies for the synthesis of GNRs of different aspect ratios and sizes are discussed here.

Methods for the synthesis of GNRs

GNRs can be synthesized by either wet or dry chemistry. Wet chemistry is the preferred mode of synthesis because of its simplicity and low costs.⁴⁵ In the following subsections, three major synthesis methods are reviewed: the template method, the electrochemical method, and the seed-mediated growth method (Figure 3).

Template method

The template method for synthesis of GNRs involves electrochemical deposition of gold onto the pores of an alumina template membrane or nanoporous polycarbonate. The method was originally used to prepare microscopic electrodes by depositing gold onto a polycarbonate

membrane using electroplating. Genzel et al were the first to successfully employ the template method for the synthesis of GNRs.⁴⁶

The method involves four steps. In the first step, copper is sputtered onto an alumina template. In the second step, gold is electrodeposited onto the nanosized pores of alumina. In the third step, the alumina membrane and copper film are dissolved in the presence of an appropriate stabilizer. In the final step, GNRs are dispersed in water or an organic solvent using ultrasonic waves or agitation. GNRs of various diameters and lengths have been successfully generated using the template method. The diameter of nanorods is controlled by the pore diameter of the template, and the length is controlled by the quantity of gold deposited within the membrane nanopores.⁴⁵

Electrochemical method

The electrochemical method is the most commonly used method for the synthesis of transition metal clusters in an organic solvent. Nikoobakht et al developed the application of an electrochemical method for the synthesis of GNRs and synthesized GNRs in high yields.⁴⁷ The actual synthesis was conducted in an electrochemical cell containing two electrodes. In the cell, a gold metal plate was used as anode, and a platinum plate was used as cathode. The final electrolysis was carried out in the presence of a hydrophilic cationic surfactant and a controlled current mode for 30–60 minutes to successfully synthesize GNRs.⁴⁷

A recent study used a silver plate to control the aspect ratio of GNRs.⁴⁸ Silver metal reacted with gold ions to generate silver ions at the anode. The amount of silver

Figure 3 Methods for the synthesis of gold nanorods.

ions and their release rates were found to affect the length of GNRs.⁴⁸

Seed-mediated growth method

The seed-mediated growth method has been used for decades to synthesize monodispersed metal nanoparticles. Brown et al were the first to use the seed-mediated growth method for the synthesis of GNRs by reducing auric gold (Au^{3+}) with hydroxylamine.⁴⁹ One of the major biocompatibility issues of the seed-mediated growth method is the formation of nanoparticles of other shapes along with nanorods.

Jana et al synthesized GNRs using 3.5 nm seed nanoparticles.⁵⁰ The yield of this method was 4%, but it was later improved by changing the pH of the growth solution from 2.8 to 5.6. The change in pH resulted in formation of GNRs with an aspect ratio between 18 and 20 and a yield of 90%.⁵¹ Hu et al used various temperatures and capping agents for GNR synthesis.⁵² It appeared that a reduced temperature and the use of hexadecyltrimethylammonium bromide as capping agent led to nanorods with an aspect ratio between 1 and 6 and a yield in the order of 50%. The study also suggested that stability of seeds, growth temperature, and concentration of surfactant influence monodispersity, yield, and aspect ratio.

The seed-mediated growth method does not only generate nanorods but also nanoparticles of various shapes. For this reason, separation of nanorods from other nanoparticles is critical. Methods such as size-selective precipitation, nanoporous filtration, and methods for extraction have successfully separated nanospheres of different sizes but are not very selective for nanorods due to their relatively large size.^{53,56} Wei et al demonstrated that size-exclusion chromatography can separate nanorods from spheres, but this method is only partly successful.⁵⁴ Jana used phase-separation involving surfactant-assisted ordering.⁵⁵ The method successfully separated single-sized nanorods from a mixture of differently-sized rods, spheres, and plates. More recently, Sharma et al demonstrated centrifugation as an efficient technique to separate nanorods from a mixture of nanorods and nanospheres.⁵⁶ The technique is based on the fact that shape-dependent drag causes particles to have shape-dependent sedimentation behavior.

Methods for the surface modification of GNRs

GNRs synthesized using the above mentioned methods have dispersion and biocompatible flaws and therefore need further surface modification before use as

hyperthermia agents.⁵⁷ There are two main strategies for surface modification of GNRs: matrix entrapment and ligand exchange.

Matrix entrapment

Entrapment of GNRs in a matrix improves their dispersion and optical and chemical characteristics. Mitamura et al entrapped and dispersed GNRs in an alginate matrix using energy dispersive X-ray spectroscopy. Alginate entrapped GNRs were highly dispersed and maintained their optical character.⁵⁸ Apart from alginate, poly(N-isopropylacrylamide) gel has also been used to disperse GNRs in a gel matrix. Gorelikov et al⁵⁹ and Kumar et al⁶⁰ dispersed GNRs in a poly(N-isopropylacrylamide) microgel using hybridization. The resulting hybrid gel was unique in that it was able to reversibly shrink with or without infrared radiation.

Ligand exchange

Surfactants used in the seed-mediated growth method for synthesis of GNRs are toxic. Ligand exchange has been the method of choice for removal of residual surfactants from GNRs. Gentili et al used a double phase transfer process for surface functionalization of GNRs.⁶¹ The process consisted of a simple one-step ligand exchange in a hydroalcoholic mixture with thiols and a phase transfer to entrap gold nanoparticles into polyethylene glycol-based polymeric nanoparticles. Thus, the obtained GNRs were lipophilic-free with a robust coating. Khanal et al synthesized GNRs stabilized by cetyltrimethylammonium bromide and subsequently exchanged the cetyltrimethylammonium bromide for a functional thiol using 4-mercaptophenol.⁶² The method resulted in formation of anisometric GNRs that self-assembled into ring-like superstructures.

Carbon nanotubes

Carbon nanotubes (CNTs) were first observed in 1952 by Radushkevich and Lukyanovich, but only in 1991 was a methodology for the synthesis of CNTs described by Iijima using C60 carbon molecules.^{63,64} CNTs are most commonly synthesized from allotropes of carbon in two different forms, such as single-walled carbon nanotubes (SWNTs) and multi-walled nanotubes (MWNTs). SWNTs consist of a single tube of graphene, and MWNTs consist of several concentric tubes of graphene (Figure 4). Both forms have unique physical and chemical properties that enable their application in anticancer hyperthermia therapy. CNTs generate heat upon infrared irradiation. Another salient feature of CNTs is the

Figure 4 Structural arrangement of carbon in (A) single-walled nanotube and (B) multiwalled nanotube.

possibility to engineer their surface for conjugation with a wide variety of molecules.⁶⁴

Methods for synthesis of CNTs

There are three major techniques for the synthesis of CNTs: arc discharge, laser ablation, and chemical vapor deposition (CVD). Arc discharge and laser ablation were the initial techniques used to synthesize CNTs. Both techniques require high temperatures (generally $>1,700^{\circ}\text{C}$) and are now more or less obsolete, replaced by CVD which is carried out at comparatively low temperatures ($<800^{\circ}\text{C}$) and enables the synthesis of CNTs with controlled orientation, alignment, length, diameter, and density.⁶⁵

Arc discharge

Arc discharge is a gas phase reaction process requiring high temperatures for synthesis of CNTs. The advantage of arc discharge is that CNTs with minimal imperfections and structural defects are generated. The process conditions are different for the synthesis of MWNTs and SWNTs.

Synthesis of MWNTs

Graphite electrodes are used for synthesis of MWNTs. The electrodes have a diameter of 8–12 nm and are water cooled. The reaction atmosphere consists of helium, hydrogen, or methane. The purity and yield of CNTs are found to vary with the gas atmosphere and pressure inside the reaction vessel. Wang et al used evaporation in methane under high pressure and high arc current to obtain thick nanotubes.⁶⁶ Lowering the methane pressure and the current at the anode

resulted in formation of thin and long MWNTs. Zhao et al used hydrogen gas instead of methane as reaction atmosphere and also obtained thin and long MWNTs.⁶⁷

Another technique for arc discharge deposition is the use of pulsed current rather than direct current. Parkansky et al used a single-pulse arc to produce MWNTs with a diameter of 10 nm and a length of 3 μm .⁶⁸ In addition to standard arc deposition, alternative methods have been used for synthesis of CNTs. Sornsuwit et al⁶⁹ and Montoro et al⁷⁰ used arc discharge in an aqueous vanadic acid solution to grow high quality SWNTs and MWNTs. Jung et al used arc discharge in the presence of liquid nitrogen to successfully grow MWNTs.⁷¹

Synthesis of SWNTs

Unlike MWNTs, SWNTs cannot be synthesized in the absence of a transition metal catalyst. The most commonly used method for the synthesis of SWNTs is based on an arc discharge system fitted with a composite anode. The composite anode consists of graphite and a combination of transition metals as catalyst. The catalyst plays an important role in increasing the yield of the process while high efficiency is ensured by a constant gap between electrodes.

Iijima et al were the first to synthesize SWNTs in 1993.⁷² Later that year, Bethune et al utilized coevaporation of carbon and cobalt to generate SWNTs with a single atomic layer.⁷³ Chen et al modified the electric arc technique for the synthesis of SWNTs by using a ferrum-hydrogen arc discharge.⁷⁴ This new technique used hydrogen arc discharge with a carbon anode containing a 1% iron (Fe) catalyst in a mixed hydrogen-argon gas environment to produce highly

crystalline SWNTs. The technique successfully generated SWNTs with a purity >90%. Fan et al further modified this technique to develop an economic process for the synthesis of SWNTs.⁷⁵ The technique used argon as reaction atmosphere and direct current arc discharge with charcoal as carbon source and iron sulfide and cobalt oxide as catalyst. SWNTs thus formed were highly pure with a diameter of 1.2 nm.

CVD

Arc discharge enables the generation of large quantities of CNTs with minimal imperfections but with low purity. CVD on the other hand produces CNTs with predefined properties and high purity.

CVD involves catalytic decomposition of hydrocarbon or carbon monoxide feedstock, with the aid of supported transition metal catalysts to produce CNTs. The synthesis is achieved by combining a carbon source with an energy source. Most commonly used energy and carbon sources are a plasma- and resistively-heated coil, methane, carbon monoxide, and acetylene. There are three main steps in the synthesis process.⁷⁶ The first step is the cracking step, where the energy source is used to crack the gas phase molecule into atomic carbon. The second step is the diffusion step, during which cracked atomic carbon diffuses toward the substrate. The third step is the heating and coating step. During this step, diffused carbon is heated and coated with the metal catalyst while it binds to the catalyst. Excellent diameter control and growth rate can be achieved with CVD. The actual process for synthesis of CNTs consists of a catalyst preparation step that is followed by the actual synthesis of the nanotube. The catalyst preparation is performed by using either sputtering or chemical etching. The temperatures for the synthesis of nanotubes by CVD are usually within the 650°C–900°C range. Typical yields for CVD are approximately 30%.⁷⁷

CVD has been used to create several structural forms of carbon, including SWNTs and MWNTs from well-crystallized graphite layers. CVD allows selective CNT growth in a variety of forms, such as powder and an aligned forest of CNTs.^{78,79}

In the last decade, different CVD-based techniques have been developed for CNT synthesis, including plasma-enhanced CVD, thermal-chemical CVD, alcohol-catalytic CVD, vapor phase growth, aero gel-supported CVD, and laser-assisted CVD.⁸⁰

Hyperthermia with MNPs Hyperthermic therapy

Hyperthermia using MNPs is often referred to as MHT. MHT involves injection of iron oxide nanoparticles inside the tumor and subsequent placement of the patient in an alternating

magnetic field, which results in an increased intratumoral temperature, thermal ablation of tumor cells, and subsequent tumor shrinkage.

MHT is advantageous in two ways. First, MNPs accumulate in the tumor. Therefore, healthy tissue damage is limited. Second, MHT is noninvasive and capable of inducing hyperthermia in tumors at any location in the body. However, the efficiency of therapy is highly variable and often found to be dependent on particle properties, including size, magnetization, and Curie temperature. Curie temperature is an important parameter, indicating the maximum temperature of a magnetic particle. A good estimate of the Curie temperature allows an efficient temperature control and is thus critical to avoid overheating of tissue by MNPs. Besides particle properties, other parameters that play an important role in determining efficiency of MHT are intensity and frequency of the alternating magnetic field and the dissipation of heat from the tumor.

The effectiveness of MHT in glioma was first reported by Shinkai et al.⁸¹ In their first study, the group used an *ex vivo* rat model implanted with glioma cell pellets and magnetic cationic liposomes. Three doses of alternating magnetic field for 60 minutes each, at intervals of 12 hours were applied to the rats. The treatment was reported to completely inhibit tumor development for up to 90 days.⁸¹ In the second study, an *in vivo* rat model was used to examine the effect of hyperthermia in glioma tumors.⁸² Magnetite cationic liposomes were administered to rats, and histological analysis revealed that the rats that were exposed to the magnetic field showed a homogeneous distribution of magnetite cationic liposomes, which also coincided with the necrotic regions. In the third study, an *in vivo* model of rat with glioma tumors was used to study antitumor immunity of rats by hyperthermia therapy.⁸³ During the primary treatment, three doses of 30 minutes each were applied at 24-hour intervals. Tumor tissue was completely eliminated in two-thirds of the rats. These rats were rechallenged with glioma cells 3 months later. Transient growth was observed in the initial 2 weeks, but the tumors disappeared in 4 weeks. The explanation for this phenomenon was promotion of anti-tumor response by activation of heat shock proteins (see below).

In the last two decades, other studies have also demonstrated the effectiveness of MHT, on its own as well as in combination with other therapies. Ito et al observed that hyperthermia promotes an anti-tumor immune response by activation of heat shock proteins.⁸⁴ In a later study, it was suggested that hyperthermia in combination with gene therapy is an effective strategy for the treatment of GBM.⁸⁵ Le et al demonstrated increased effectiveness of

magnetite cationic liposomes in the destruction of GBM tissue by conjugating magnetic cationic liposomes to a specific antibody against GBM.⁸⁶ Table 2 shows a comprehensive list of *in vivo* studies that evaluated SPIONs for GBM treatment.

Latest clinical trials in Europe suggest that the application of magnetic hyperthermia may become clinically effective soon. MagForce Nanotechnologies (Berlin, Germany) has developed a MHT system called “NanoTherm®.” The system is based on aminosilane-coated SPIONs and the application of an alternating magnetic field. This MHT system has received approval in Europe to use iron oxide MNPs for GBM treatment.⁸⁷

Hyperthermia as enhancer of drug delivery

The term “hyperthermia” has thus far been confined to the use of heat for therapy. However, hyperthermia has also been utilized as a novel mechanism to improve drug delivery to tumors.⁸⁸ The use of magnetic field to control drug release from polymeric matrices containing iron oxide was first reported nearly 30 years ago.^{88,89} The MNP design for drug delivery is unique and generally consists of an iron oxide core and a polymer shell. The polymer shell is heat sensitive, and upon heat transferred from the iron oxide core, it contracts to release the encapsulated drug. MNP systems based on this concept are able to deliver drugs in a controlled manner. Control is possible because of the sensitivity of the MNP shell to a magnetic field, which is a function of frequency and strength of alternating magnetic field.⁹⁰

Hyperthermia-mediated release of various drugs was first demonstrated using temperature-sensitive poly(*N*-isopropylacrylamide) hydrogels incorporating SPIONs.⁹¹ Hoare et al demonstrated on-demand release of sodium fluorescein using nanocomposite membranes of thermosensitive poly(*N*-isopropylacrylamide)-based nanogels and magnetite nanoparticles⁹² (Figure 5). This

study opened avenues for the development of therapeutic systems such as magnetic micro- and nanopumps, magnetic field-controlled drug delivery devices, and magnetic switches.

A more recent design of a magnetic drug delivery platform is magnetic composite nanoparticles consisting of multiple metals. Behrens et al demonstrated the potential of ferromagnetic cobalt nanoparticles in modulating the permeability of polyelectrolyte microcapsules.⁹³ In this study, ferromagnetic gold-coated cobalt nanoparticles were embedded inside polymeric walls using the layer-by-layer self-assembly technique. The polymer capsules consisted of eleven layers, with one layer of ferromagnetic gold-coated cobalt nanoparticles and ten layers of polyelectrolyte bilayers. The polymer capsule design was found to be ideal for the magnetic control of the permeability of the composite nanoparticle.

Another interesting type of MNPs for drug delivery is iron-core and silica-shell nanoparticles. This nanoparticle design is unique because it protects biomolecules that are encapsulated in the shell from the environment. The core-shell nanoparticles resemble extracellular vesicles. Extracellular vesicles are small granules that are produced by cells in our body to deliver biological materials to recipient cells.⁹⁴

More recently, implantable microchips have been developed on the basis of MNPs, such as a novel drug-delivery chip for magnetically-controlled release of anti-epileptic drugs^{95,96} (Figure 6). The chip was made of an electrically-conductive flexible polyethylene terephthalate substrate that contained drug-loaded magnetic SPION-core-silica-shell nanoparticles.

Hyperthermia with GNRs Hyperthermic therapy

Gold nanoparticles possess unique optical properties of which surface plasmon resonance is the most important.

Surface plasmon resonance is the collective oscillation of electrons in a solid or liquid state stimulated by incident light. In the case of gold nanoparticles, absorption of infrared light induces surface plasmon resonance that is converted

into heat. GNRs have the greatest potential for biomedical applications because of their high light absorption efficiency per unit volume. GNRs exhibit two distinct surface plasmon oscillations: a strong band in the near infrared region, corresponding to electron oscillation along the long axis (longitudinal band) and a weak band in the visible region (transverse band). Only the longitudinal band is sensitive to size changes and can be shifted from the visible to the near infrared region by adjusting the aspect ratio (length/width) during synthesis.⁹⁷

GNRs have attracted great interest for hyperthermic therapy due to superior biocompatibility. The effectiveness of GNRs in hyperthermic anti-tumor therapy has been demonstrated.⁹⁷ GNRs have been conjugated with molecules that carry sequences that can bind to cancer biomarkers. These GNRs specifically target and destroy tumors. Oral cancers are known to overexpress folate receptors, and therefore many studies utilized GNR conjugated with folic acid to target oral cancer cells. The study successfully ablated oral cancer cells in a targeted manner.⁹⁸ Choi et al used PEGylated GNRs conjugated with an Arg-Gly-Asp sequence to specifically bind to $\alpha v \beta 3$ integrins expressed on GBM cells.⁹⁹ The study demonstrated that (Arg-Gly-Asp)-GNRs are able to circulate for prolonged periods of time and bind to GBM cell surface, thus targeting GNRs to the GBM tumor. Fernandez et al developed an optical hyperthermia method for treatment of GBM by irradiation of GNRs by laser light and was successful in ablating GBM cells in vitro.¹⁰⁰ Oli et al used folate-conjugated GNRs to specifically target GBM cells.¹⁰¹ The study showed that folate-conjugated GNRs can successfully target and kill GBM cells upon excitation with a near infrared laser.

Hyperthermia as enhancer of drug delivery

GNRs have also been studied as enhancers of drug delivery. GNRs offer tunable and localized surface plasmon resonance, which makes them highly localized heat sources when irradiated with a laser. The heat generated by GNRs is used for hyperthermic cancer therapy and/or to trigger the release of a drug.

Although drug delivery using GNRs is a new field, there are two major studies that investigated the use of GNRs to deliver doxorubicin to GBM. Agarwal et al were the first to study remotely triggered release of doxorubicin in GBM tumors using thermosensitive liposomes and GNRs.¹⁰² PEGylated GNRs triggered release of doxorubicin from thermosensitive liposomes in a mouse tumor model of human GBM when irradiated with near infrared light. The stimulation resulted in significantly increased efficacy when compared to nontriggered or nonthermosensitive PEGylated liposomes. More recently, Xiao et al studied GNRs conjugated with doxorubicin and cyclo(Arg-Gly-Asp-D-Phe-Cys) peptide for drug delivery in GBM.¹⁰³ Doxorubicin was covalently conjugated to PEGylated GNRs via a hydrazone bond. Flow cytometric analysis revealed that GNRs conjugated with doxorubicin and cyclo(Arg-Gly-Asp-D-Phe-Cys) peptide exhibited a higher cellular uptake and cytotoxicity than nontargeted GNRs conjugated with doxorubicin in human GBM cells.

Zhang et al evaluated the potential of mesoporous silica-coated GNRs for cancer theranostics in a proof of concept study in human alveolar adenocarcinoma cells.¹⁰⁴ The core of GNRs functioned both as an agent that allowed noninvasive imaging as well as a hyperthermic agent while the outer mesoporous silica shell encapsulated a high drug load, thus posing itself as an effective drug carrier (Figure 7).

Hyperthermia with CNTs

Hyperthermia using CNTs is a new field compared to MNP- and GNR-mediated hyperthermia. CNTs exhibit unique physical and chemical properties that hold promise for drug delivery and cancer therapy.¹⁰⁵ The mechanisms of selective tumor targeting with CNTs are currently being explored due to their impressive ability to convert near infrared light into heat. This intrinsic property of CNTs opens new avenues for the development of novel nanostructures for cancer phototherapy.¹⁰⁵

Markovic et al used CNTs and graphene nanoparticles for hyperthermic ablation of human glioma cells *in vitro*.¹⁰⁶ The study showed that graphene nanoparticles triggered cell death by inducing oxidative stress, and CNTs triggered cell

Figure 7 Mechanism of action of mesoporous silica-coated gold nanorods (A), gold nanorods without coating (B), and mesoporous silica-coated GNRs (C).

Notes: The core of GNRs functioned both as an agent that allowed noninvasive imaging as well as a hyperthermic agent while the outer mesoporous silica shell encapsulated a high drug load, thus posing itself as an effective drug carrier. Reproduced from Zhang Z, Wang L, Wang J, et al. Mesoporous silica-coated gold nanorods as a light-mediated multifunctional theranostic platform for cancer treatment. *Adv Mater.* 2012;24(11):1418–1423.¹⁰⁴ Copyright © 2012 WILEY-VCH Verlag GmbH & Co. death via mitochondrial membrane depolarization. Wang et al incubated GBM cells with anti-CD133 monoclonal antibody-conjugated SWNTs,¹⁰⁷ and irradiation with near infrared laser light resulted in targeted ablation of GBM cells while the viability of control cells remained unaffected. In a second study, Wang et al generated anti-GD2-conjugated CNTs to target GD2 receptors present on the surface of neuroblastoma cells.¹⁰⁸ Neuroblastoma cells were pretreated with anti-GD2-conjugated CNTs and were then irradiated with a near infrared laser. Postexposure analysis revealed necrosis among GD2-positive cells, whereas GD2-negative (control) cells remained unaffected. These studies suggest that SWNTs and MWNTs possess unique optical

properties that have potential to develop novel therapies for the treatment of GBM.

Conclusion

GBM is an aggressive tumor type with very low survival rates. Many factors attribute to the low survival rates; some are inherent while others are treatment dependent. Conventional therapies lack specificity for cancer cells and therefore lead to side effects. Conventional therapies in combination with alternative or adjuvant therapies provide a better treatment strategy but still lack the efficacy and potential that is needed for effective treatment of GBM.

Conventional hyperthermia with external devices has been used for a long time but lacks accurate temperature control, leading to overheating and damage of healthy tissue or dissipation of heat from the tissue. Hyperthermia using nanoparticles is a novel concept that enables controlled heating of tumor tissue. Nanoparticle-based hyperthermia can have direct therapeutic effects and enhance drug delivery in a single therapy, making it a therapy with two advantages for cancer treatment.

MNPs, GNRs, and CNTs are the most promising nanoparticles for hyperthermic therapy in GBM. Among MNPs, SPIONs are the nanoparticles of choice for treatment of GBM. The salient features of SPIONs are:

- ease of synthesis;
- superior biocompatibility; and
- relatively low cost.

Cationic liposomes and aminosilane-coated SPIONs have been found to be effective in ablating GBM in the presence of an alternating magnetic field. MagForce Nanotechnologies has commercialized MHT for the treatment of GBM after successful Phase I, II, and III trials.

In addition to high treatment efficacy, many studies^{81,82} have also confirmed an antitumor immune response after hyperthermia, based on elevated expression of heat shock proteins, which is an added advantage.

Core-shell SPIONs, when incorporated with drugs and stimulated with alternating magnetic field, are capable of drug delivery in a controlled manner. Layer-by-layer self-assembly is the preferred method for synthesis of core-shell SPIONs. Drug delivery and hyperthermia using SPIONs is promising yet challenging. Advantages of SPION-based hyperthermia are:

- ability to cross the blood–brain barrier;
- delivery through multiple routes;
- minimal or no side effects;

- noninvasive procedure; and
- antitumoral immunity.

Some of the challenges on the other hand are moderate to low absorption rates, monitoring temperature distribution, self-regulation of heating, and precise control of intratumoral temperature.

Gold nanoparticles exhibit exceptional physical and optical properties including surface plasmon resonance. These properties enabled the development of novel photothermal therapies for the treatment of GBM. GNRs encompass better properties than gold nanospheres including superior biocompatibility and higher light absorption per unit volume.

GNRs are prepared by either wet or dry chemistry. Wet chemistry is the preferred mode due to the simple and inexpensive nature of synthesis. Most investigated wet chemistry-based methods for GNR synthesis are:

- template;
- electrochemical; and
- seed-mediated growth.

When GNRs are intravenously injected in *in vivo* models of GBM and irradiated with near infrared laser light, they cause significant thermal ablation of tumor cells via necrosis and/or apoptosis. This procedure is successful in reducing tumor volume but often leads to nonspecific heating of surrounding healthy tissue. Conjugation of GNRs with cell surface targeting antibodies or aptamers can overcome these nonspecific heating effects. Studies have successfully used $\alpha v \beta 3$ integrins and folate receptors to target GNRs to GBM cells.

Core-shell GNRs are versatile nanocarriers for drug delivery. Studies have successfully delivered doxorubicin as model drug to GBM cells using targeted as well as nontargeted approaches.

In summary, core-shell versions of GNR are capable of:

- controlled drug delivery;
- hyperthermia; and
- combinational therapy.

Development of multifunctional systems based on core-shell MNPs and GNRs with individual functions acting in a coordinated way is critical to optimize therapeutic efficacy and safety of therapeutic regimes, and could provide more opportunities for on-demand therapy and pave the road toward personalized medicine.

CNTs and graphene nanoparticles exhibit an impressive ability to convert near infrared light into heat. This intrinsic property of CNTs is utilized to develop hyperthermic therapy

for GBM treatment. The studies suggest that CNTs and graphene nanoparticles can effectively ablate glioma cells in a targeted as well as a nontargeted manner. Although CNTs are successful in cancer phototherapy, further studies are needed to elucidate all mechanisms involved in CNT-mediated anticancer therapy.

Among MNPs, GNRs, and CNTs, SPIONs are promising in the development of MHT, GNRs are promising in the development of photodynamic therapy, and CNTs have potential in the development of photothermal therapy for the treatment of GBM.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>

Dovepress

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
