## Abstract

**Background:** Cardiovascular disease with disturbances in the haemostatic system, might lead to thrombotic complications with clinical manifestations like acute myocardial infarction (AMI) and stroke. Activation of the coagulation cascade with subsequent increased thrombin generation, characterizes a prothrombotic phenotype. In the present study we investigated whether prothrombotic markers were associated with risk factors and clinical subgroups in a cohort of patients with angiographically verified coronary artery disease (CAD). The patients were randomized to long-term treatment with the antiplatelet drugs aspirin or clopidogrel, and we further investigated the effect on hypercoagulability of such treatment for 1 year, of which limited data exists.

**Methods:** Venous blood samples were collected in fasting condition between 08:00 and 10:30 am, at baseline when all patients were on aspirin therapy ( $n=1001$ ) and in 276 patients after 1 year follow-up on aspirin or clopidogrel. In vivo thrombin generation was assessed by prothrombin fragment 1 + 2 (F1+2) and D-dimer, and the endogenous thrombin potentiale (ETP) in the calibrated automated thrombogram (CAT) assay, representing ex vivo thrombin generation. In addition soluble tissue factor (sTF) and free- and total tissue factor pathway inhibitor (TFPI) were measured.

**Results:** We found age to be significantly associated with F1+2 and D-dimer ( $\beta=0.229$  and  $\beta=0.417$  respectively,  $p <0.001$ , both). Otherwise, only weak associations were found. F1+2 and D-dimer were higher in women compared to men ( $p <0.001$  and  $p=0.033$ , respectively). Smokers had elevated levels of ETP compared to non-smokers ( $p=0.014$ ). Additionally, patients on renin-angiotensin system (RAS) inhibition showed significantly higher levels of F1+2, compared to non-users ( $p=0.013$ ). Both aspirin and clopidogrel reduced levels of ETP after 12 months intervention ( $p=0.003$  and  $p <0.001$ , respectively) and the levels of F1+2 were significantly more reduced on aspirin compared to clopidogrel ( $p=0.023$ ).

**Conclusions:** In the present population of stable CAD, we could demonstrate a more hypercoagulable profile among women, smokers and patients on RAS medication, assessed by the prothrombotic markers F1+2, D-dimer and ETP. Long-term antiplatelet treatment with aspirin alone seems to attenuate thrombin generation to a greater extent than with clopidogrel alone. The study is registered at [www.clinicaltrials.gov](http://www.clinicaltrials.gov): NCT00222261.

## Background

Cardiovascular disease (CVD) is a global burden in which thrombotic complications play a major role [1]. The underlying mechanism of CVD is mainly the atherosclerotic process, characterized by lipid accumulation in the subendothelium causing a low graded inflammatory lesion and changing the phenotype of the endothelium to a pro-inflammatory and pro-thrombotic state [2].

Disruption of lesions expose atherogenic material into the arterial lumen. Platelets adhere, aggregate and become activated which may lead to thrombus formation. An occluded vessel may cause clinical manifestations like acute myocardial infarction (AMI) and stroke [3].

Expression of subendothelial tissue factor (TF) with subsequent activation of the coagulation cascade generates thrombin at the surface of activated platelets [2,3]. TF interacts with coagulation factor VII, forming an active complex which activates both FIX and FX. FXa is responsible for the proteolytic cleavage of prothrombin to thrombin, resulting in formation of prothrombin fragment 1+2 (F1+2) and further the formation of fibrin. TF is abundantly present in atherosclerotic plaques. In addition soluble TF (sTF) may be found on monocyte- or platelet- derived microparticles or sTF may be released from cells. The initiation of coagulation is regulated by tissue factor pathway inhibitor (TFPI) which inhibits both TF-FVIIa complex and activated FX [4,5]. The pro- and anticoagulant balance is essential in the prevention of thrombotic complications. Increased levels of the haemostatic markers sTF, F1+2 and D-dimer, the latter reflecting ongoing fibrin formation and degradation, have been shown in patients with CVD, whereas the role of TFPI in CVD is less clear [6].

Recently, the endogenous thrombin potential (ETP) measured by the calibrated automated thrombogram (CAT) assay, has been proposed to be an informative research tool to study the degree of hypercoagulability [7]. There are however, limited data on the association between CAT measures and CVD risk factors.

Patients with coronary artery disease (CAD) are routinely treated with antiplatelet medication, of which aspirin is most commonly used. Aspirin suppress the cyclooxygenase pathway in the arachidonic acid metabolism and has also been shown to possess anti-inflammatory properties probably by inactivating NF-kappa B [8,9]. Recently other anti-platelet drugs have become common in use, for instance clopidogrel, a thienopyridine, blocking the ADP-pathway. Since activated platelets act as a catalytic surface for thrombin generation, anti-platelet treatment in general, might have an anticoagulant effect, with a decline in generated thrombin [10]. However, limited knowledge of any effects on prothrombotic markers of clopidogrel exists.

The aim of the present study was to investigate whether prothrombotic markers were associated with

traditional risk factors, and clinical subgroups in a large population with stable CAD. The state of hypercoagulability was assessed by measures of sTF and TFPI, and F1+2, D-dimer and the CAT assay, the latter as marker of ex vivo thrombin generation.

We further wanted to explore the long-term effect of single clopidogrel as compared to single aspirin treatment on hypercoagulability in the same population, with the hypothesis that patients randomized to aspirin were less procoagulant.

## Methods

### Study subjects

A total of 1001 patients with angiographically verified stable CAD were enrolled in the ASpirin non-responsiveness and Clopidogrel clinical Endpoint Trial (ASCET) [11] at Oslo University Hospital, Ullevål, from 2004–2008. At inclusion all patients were on aspirin only and had been treated with aspirin only (160 mg/day) at least one week. Patients were thereafter randomized to either continuous treatment with aspirin or to change to clopidogrel (75 mg/day) and the patients were further followed for two years. The present sub-study is based on data from baseline examinations in the total population and from the one-year follow up in a sub-set of 300 consecutively enrolled patients.

The study is in accordance with the principles of the declaration of Helsinki and is approved by the Regional Ethics Committee, and all patients have given written informed consent to participate. The study is registered at [www.clinicaltrials.gov](http://www.clinicaltrials.gov): NCT 00222261.

### Clinical subgroups

Within the population, previous myocardial infarction (MI) was recorded by patients' medical files, and hypertension (HT) was defined as previously diagnosed and treated HT. Diabetes included individuals with treated type 2 diabetes (T2DM) and/or fasting glucose >7.0 mmol/L. The metabolic syndrome (MetS) was defined according to the American Heart Association/National Heart, Lung and Blood Institute [12]. Smoking habits were recorded as current smokers or not. Ex-smokers were included as non-smokers if they had quit smoking >3 months ago.

### Blood sampling

Venous blood samples were drawn in fasting condition between 08:00 and 10:30 am before intake of morning medication. Blood was collected in Vacutainer tubes containing 0.129 M trisodium citrate in dilution 1:10. The samples were stored on ice and centrifuged at 3000 x g for 20 min at 4°C within 1 hour. Plasma was kept frozen at -80°C until analyzed. Blood samples for

routine analysis (glucose, HbA1C and lipids) were prepared and analyzed with conventional methods.

### Laboratory methods

Levels of sTF, TFPI, F1+2 and D-dimer were assessed by commercially available enzyme immunoassays; Imubind TF kit recognizing TF-apolipoprotein, sTF and TF-VII complexes (American Diagnostic Inc., Greenwich, Conn., USA), Aserachrom free and total TFPI antigen, recognizing full-length and full-length and truncated TFPI molecules associated to lipoproteins, respectively (Stago Diagnostica, Asniere, France), Enzygnost® F1+2 (monoclonal) (Siemens, Marburg, Germany) and Assera-chrom® D-dimer (Stago Diagnostica). The coefficients of variation in our laboratory were 7.9, 5.6, 5.7 and 6.7%, respectively.

### The CAT assay

Ex vivo thrombin generation potential was investigated by the CAT assay, performed according to the manufacturer's instruction (Thrombinoscope BV, Maastricht, The Netherlands). The method is described in detail elsewhere [13]. Briefly, 80 $\mu$ l thawed platelet poor plasma (PPP) was mixed with 20 $\mu$ l of a reagent containing recombinant relipidated TF and phospholipids, with the final concentrations of 5pM and 4 $\mu$ M, respectively. Reagents were provided from Thrombinoscope BV (Maastricht, The Netherlands). The reactions were performed in micro-titre wells (Immulon 2HB transparent U-bottom from Thermo Electron, Denmark) after automatic addition of a freshmade starting reagent containing CaCl<sub>2</sub> (100 mM) and a thrombin specific fluorogenic substrate (Z-Gly-Gly-Arg-AMC) (2.5 mM) in Hepes buffer. The fluorescence intensity was recorded by the Fluoroskan Ascent® microplate fluorometer (Thermo Fisher Scientific Oy, Vantaa, Finland). By simultaneous analysis of an inert thrombin calibrator with known thrombin activity, the software program (Thrombinoscope BV, version 3.0.0.29) is enabled to display the lag-time (LT, min), peak height (PeakH, nM), the endogenous thrombin potential (ETP, nM·min) and time to peak (ttPeak, min). The inter-assay coefficients of variation for the different parameters were 14.2%, 4.6%, 5.0% and 8.0%, respectively.

### Statistical methods

Continuous data on clinical characteristic of the population were mostly normally distributed, and data are presented as mean (SD) or proportions. As most of the measured variables were not normally distributed, data are presented as median values with 25, 75 percentiles. Univariate linear regression with log transformed values when appropriate, were used to analyse for associations between variables of thrombin generation and traditional

risk factors. Linear regression models were also used to adjust for potential covariates in group comparisons.

Mann-Whitney U test or chi square test for categorical data were applied for group comparisons, and Wilcoxon's test was used for within group changes. For difference in changes between the intervention groups, Mann-Whitney U test was used. P-values  $\leq 0.05$  were considered statistically significant. The statistical analyses were performed by SPSS Inc PASW statistics, version 18.

### Results

Clinical and laboratory characteristics of the total study population at baseline ( $n = 1001$ ) are shown in Table 1. Mean age was 62 years and 22% of the patients were women. The patients were optimally treated, all receiving aspirin, 98% on statins, 76% on beta blockers and 50% on angiotensin converting enzyme inhibitors (ACEI) or angiotensin receptor blocker (ARB).

**Table 1 Baseline characteristics of the total study population ( $n = 1001$ )**

Age <sup>1</sup> (years (range))	62 (36–81)
Male / Female (n (%))	783/218 (78/22)
Hypertension (n (%))	555 (55)

## Associations

Associations between traditional risk factors and variables of thrombin generation are presented in Table 2. Age was significantly associated with F1+2 and D-dimer ( $p < 0.001$ , both). Otherwise, only weak associations were found. For parameters in the CAT assay no significant associations were found (data not shown). Only results of ETP from the CAT assay are presented further.

## Thrombin generation in subgroups of CAD

The associations between different subgroups and sTF, free and total TFPI have previously been reported [14]. Markers of thrombin generation according to subgroups are presented in Table 3. Gender differences were observed for F1+2 and D-dimer, showing women to have higher levels, also after adjustment for covariates (age, BMI and HDL-cholesterol) ( $p < 0.001$  and  $p = 0.033$ , respectively). Smokers had significantly higher levels of ETP as compared to non-smokers (adjusted  $p = 0.014$ ). In patients having MetS increased levels of ETP, but lower levels of F1+2 were observed. However, these differences were abolished after adjustments for covariates. No significant differences in any variables were observed with respect to having T2DM or not or whether they had experienced a MI or not.

In univariate analyses significantly higher levels of F1+2 and D-dimer were observed in patients with HT, however, not statistically significant in multivariate analyses. A high number of patients were on ACEI and/or ARBS ( $n = 495$ ) and in these patients compared to non-users, significantly higher levels of F1+2 and D-dimer were found. When adjusted for covariates, including creatinine, F1+2 levels were still significantly elevated ( $p = 0.013$ ). No differences in any variables in patients using beta-blockers or not were observed.

## Influence of aspirin and clopidogrel on markers of coagulation

In the subset of patients ( $n = 300$ ) of which 276 were available for re-investigation after 12 months, baseline characteristics did not differ between the randomized groups (Additional file 1: Table S1). Of the measured variables significantly higher levels of sTF in the clopidogrel group were found at baseline ( $p < 0.01$ ) (Table 4). After 12 months intervention, significant reduction in F1+2 ( $p = 0.029$ ) and ETP ( $p = 0.003$ ) were observed within the aspirin group, whereas a slight, but statistically significant increase in sTF ( $p = 0.029$ ) and free TFPI ( $p < 0.001$ ) were recorded. In the group randomized to clopidogrel, significantly reduced levels of ETP were found ( $p < 0.001$ ), while levels of free TFPI increased ( $p = 0.035$ ). When comparing the changes between the

**Table 4 Markers of coagulation at baseline (all patients on aspirin) and after 12 months continuing on aspirin or randomized to clopidogrel**

Median values (25, 75 percentiles) are given.

\* refers to differences between groups at baseline ( $p < 0.01$ ).

p1 and p2 refer to differences from baseline to 12 months in the aspirin and clopidogrel groups, respectively.  $\Delta p$  refer to difference in changes between groups from baseline to 12 months.

† refers to difference in relative changes from baseline to 12 months

groups, the reduction in F1+2 levels in the aspirin group was significantly different from the unchanged values in the clopidogrel group ( $p = 0.023$ ). As for sTF the slight increase in the aspirin group was significantly different from the non-significant reduction in the clopidogrel group ( $p = 0.032$ ). When taking the baseline levels into account by analyzing the difference in relative changes, the difference in change was still statistically significant ( $p = 0.042$ ).

## Discussion

In the present study on patients with stable CAD we could show that age was significantly associated to in vivo thrombin generation assessed by F1+2 and D-dimer. These markers were both higher in women than in men, and smokers had elevated levels of ex vivo thrombin generation measured by ETP, compared to non-smokers. Patients on ACEI and/or ARBS had significantly higher levels of F1+2 compared to non-users.

After one year treatment with either aspirin or clopidogrel, ETP levels were significantly reduced in both groups, and a significant reduction in F1+2 levels was observed on aspirin in contrast to on clopidogrel. The limited conformity between the investigated markers of in vivo and ex vivo thrombin generation, indicate that ongoing in vivo coagulation may not necessarily be compatible with a higher potential for ex vivo thrombin generation.

### Thrombin generation in subgroups of CAD

Among the traditional risk factors we found age to be strongest associated with the prothrombotic markers F1+2 and D-dimer. These results are in line with previous reports, demonstrated in a wide age span in healthy individuals [15]. Although these markers are known to be unspecific among the elderly, the risk of CVD in general is more pronounced with advancing age, partly due to an imbalance in the haemostatic system [16].

Regarding age and ex vivo thrombin generation (ETP) we could not find any association. This is in contrast to some previous reports, however, performed in quite different populations [17,18]. The discrepancy might be due to the rather large inter-individual variations reported for this assay, which may mask potential differences [7].

The women in our population were older compared to men, and they presented with higher levels of F1+2 and D-dimer, also after adjustment for age. ETP levels were, however not affected. This is in line with results from another similar group reporting elevated levels of prothrombotic markers in women compared to men [19]. Most of our women were postmenopausal, which also is associated with an adverse influence on traditional cardiovascular risk factors [20].

We demonstrated increased ex vivo thrombin generation assessed by ETP in smokers. To the best of our knowledge this has not been reported on before. In an Italian study it was shown a reduction in F1+2 and D-dimer levels after smoking cessation in individuals free from cardiovascular risk factors [21]. It is well-known that tobacco smoke increases platelet aggregability and it is discussed to have a direct toxic effect on the endothelium, including triggering haemostatic activation and thrombosis [22,23].

We could not demonstrate any increased activation of coagulation in patients with previous MI, T2DM or HT. According to several lines of evidence such patients are discussed to be more susceptible to atherothrombotic disease [24,25]. However, all our patients were very well medically treated, i.e. all patients were on aspirin and 98% on statins. Statins have been shown to reduce hypercoagulability, which may have masked any difference [26].

Somehow unexpected, patients on renin-angiotensin system (RAS) blockade, either with ACEI or ARB's, had elevated levels of F1+2 compared to non-users,

statistically significant also after correction for renal function. RAS blockade has been shown to be protective in different patient populations [27], possibly by improved haemodynamic stability, but also by prevention of angiotensin stimulated TF-expression and inhibition of fibrinolysis [28-30]. It has been shown significant correlations between components of the RAS, and levels of D-dimer, fibrinogen and plasminogen activator inhibitor type-1 in hypertensive patients, and it was suggested that plasma renin activity was the predominant component [31]. As renin is upstream of the levels of the blockade used, the increased levels of F1+2 might be discussed to be due to less consumption of renin.

#### Effect of aspirin and clopidogrel on haemostatic markers

Data on anticoagulant effect of single antiplatelet treatment with either aspirin or clopidogrel, are sparse and conflicting. We demonstrated reduced thrombin generation, measured by ETP and F1+2, after long-term treatment with aspirin (160 mg/d), the latter being different from the changes on clopidogrel. This can be seen as contradictory to the CAPRIE trial in which clopidogrel was found to be slightly more effective compared to aspirin [32]. In this trial it should be noted that there were no difference in outcome between aspirin- or clopidogrel-treated patients entering the study with CAD, being present in all our patients. In addition to different mechanisms for inhibition, the patient population may thus also play a role for the effectiveness. In the present study, only effects on haemostatic markers were investigated. The effects on thrombin generation could potentially be ascribed to anti-inflammatory actions of aspirin. However, we have previously shown no difference in CRP-levels between the aspirin and clopidogrel groups in this cohort [9].

The decline in ETP could be explained by change in the assembly of pro- and anticoagulant factors after long-term treatment [13,33]. Activated platelets play a crucial role as a catalytic surface and a source for activated coagulation factor V, necessary for the large scale thrombin generation. During antiplatelet treatment this might decrease levels of F1+2, the most sensitive marker for in vivo thrombin generation [34]. Our results are in accordance with some previous reports, although, conflicting results exist [10,35].

Decreased thrombin generation by aspirin at the site of microvascular injury has furthermore been shown [36,37]. Several other mechanisms in the anticoagulant effect of aspirin have been discussed. The properties of aspirin to acetylate coagulation proteins and platelet receptors have been suggested to play a role [38]. It has moreover been shown decreased TF expression after treatment with aspirin in an experimental study related

to reduced activity of the transcription factor NF-kappa B [39,40]. In our study, we observed a small but statistically significant increase in endogenous TF after 12 months on aspirin. This was not visualized in the CAT assay, which may be due to the relatively high dose of thrombin used in the assay.

In the group randomized to clopidogrel (75 mg/d) we observed a decline in thrombin generation after 12 months, however, only shown by ETP. Limited data on single long-term clopidogrel administration exist, but anti-thrombotic properties of clopidogrel has been shown at the site of microvascular injury in CAD patients [41]. In a rat modell a 23% decrease in ETP after clopidogrel ingestion, has also been shown [42]. On the contrary, several studies including dual anti-platelet treatment have not been able to demonstrate an additional beneficial effect of clopidogrel on top of aspirin on thrombin generation [43-45]. Blocking the ADP-pathway has nevertheless been shown to decrease collagen stimulated release of TF from platelet-leukocyte aggregates, and clopidogrel alone, as well as in combination with other antiplatelet agents, was reported to decrease circulating levels of TF [46,47]. This could not be confirmed in our study. This might be discussed along with the different TF methods used [47,48].

Free TFPI levels increased in both treatment groups. Whether this elevation is a compensatory mechanism to maintain the TF/TFPI balance is not known [49]. TFPI is a major determinant of ex vivo thrombin generation tests and might therefore explain the decrease in ETP levels, seen after one year in both groups [50].

#### Conclusions

In summary, in the present population with stable CAD, we could demonstrate a more hypercoagulable profile among women, smokers and patients on RAS medication, assessed by the prothrombotic markers F1+2, D-dimer and ETP. Long-term antiplatelet treatment with aspirin alone seems to attenuate thrombin generation to a greater extent than with clopidogrel alone.

#### Competing interests

The authors declare no competing interests.

#### Authors' contributions

VB conducted the study and was responsible for the blood sampling and the ETP, D-dimer and F1+2 analyses. VB also drafted and revised the manuscript. AAP contributed to the study protocol and acquired data. TBO performed the sTF and free- and total TFPI analyses in addition to interpretation of results. HA contributed to the study protocol and discussed

the manuscript. IS conducted the study, contributed to the interpretation of results, drafted and revised the manuscript. All authors read and approved the final version of the manuscript.

#### Authors information

VB: MSc  
AAP: MD, PhD student  
TBO: MSc, PhD student  
HA: Professor, MD, PhD  
IS: Professor, PhD

#### Acknowledgements

The authors would like to thank medical laboratory technologist Sissel Åkra for excellent assistance in blood sample handling in the ASCET-study.
