Spectroscopic properties of a series of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0 \leq x \leq 0.98$ ) compounds has been studied under high hydrostatic pressure applied in a diamond anvil cell up to 200 kbar. At ambient pressure the crystal structures of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0 \leq x \leq 0.98$ ) are related to the ratio of strontium to barium and three different phases exists: orthorhombic *Pbcn* ( $0.78 \leq x \leq 0.98$ ), triclinic *P1* ( $0 < x \leq 0.65$ ) and triclinic *P1* ( $0.65 < x < 0.78$ ). It was found that  $\text{Eu}^{2+}$  luminescence reveals abrupt changes under pressure (decay time, energy and shape) which indicate the variation of the local symmetry and crystal field strength in  $\text{Eu}^{2+}$  sites. These changes are attributed to the reversible pressure-induced structural phase transitions of triclinic  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  into orthorhombic structure. Pressure in which phase transition occurs decreases linearly with increasing of Ba composition in  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  series. Additionally, very different pressure shifts of the  $\text{Eu}^{2+}$  luminescence in different phases of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2:\text{Eu}$  from  $-40 \text{ cm}^{-1}/\text{kbar}$  to  $0 \text{ cm}^{-1}/\text{kbar}$  have been observed. This effect is explained by different interaction of the  $\text{Eu}^{2+}$  5d electron with the second coordination sphere around the impurity cations.

Rare earth activated oxonitridosilicate compounds have been widely explored as advanced phosphors in white emitting diodes (WLEDs) due to very efficient and thermally stable luminescence that covers a broad spectral range, under excitation of blue and/or UV light<sup>1–5</sup>. Moreover, since these materials have been synthesized under ambient pressure they have a lower production cost than high-pressure synthesized nitridosilicates materials such as  $\text{M}_2\text{Si}_3\text{N}_8:\text{Eu}$  ( $\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$ ),  $\text{MAlSiN}_3:\text{Eu}$  ( $\text{M} = \text{Ca}, \text{Sr}$ )<sup>5–10</sup>. Among oxonitridosilicate phosphors, there is an increasing interest in layered  $\text{MSi}_2\text{O}_2\text{N}_2:\text{Eu}$  ( $\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$ ) which show efficient yellow, green and cyan emission, respectively<sup>11–17</sup>. The present research in rare-earth ions doped  $\text{MSi}_2\text{O}_2\text{N}_2$  ( $\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$ ) mainly focuses on the development of an appropriate host composition by mixing alkaline earth metal cations to adjust their emission properties. For example, structure variations in  $\text{MSi}_2\text{O}_2\text{N}_2:\text{Eu}$  ( $\text{M} = \text{Ba}, \text{Sr}$ ) with gradually substitution of Ba with Sr leads to continuous or abrupt changes in luminescence properties of these compounds<sup>14,15,18,19</sup>.

Based on high resolution synchrotron XRD measurements, it has been shown that crystal structures of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0 \leq x \leq 0.98$ ) are related to the ratio of strontium to barium. Depending on barium content three different phases exist: *Phase A* ( $0.78 \leq x \leq 0.98$ ), *Phase B* ( $0 < x \leq 0.65$ ) and *Phase C* ( $0.65 < x < 0.78$ )<sup>18</sup>. *Phase A* and *Phase B* are isostructural to well-known crystal structures of  $\text{BaSi}_2\text{O}_2\text{N}_2$  and  $\text{SrSi}_2\text{O}_2\text{N}_2$ , respectively, whereas *Phase C* adopts a distorted variation of the  $\text{BaSi}_2\text{O}_2\text{N}_2$  type structure<sup>14</sup>. The crystal structure of *Phase A* with orthorhombic unit cell is described by *Pbcn* space group, while *Phase B* with a triclinic unit cell is described by *P1* space group. *Phase C* is a new crystal structure that is different from *Phase A* and *Phase B* and can be regarded as a “transition state” between them, since it combines the unit cell-metrics of the *Phase A* type with corrugated metal-ion layers found in the *Phase B*. Nominally *Phase C* with triclinic unit cell is attributed to *P1* space group. Detailed studies on the high resolution transmission electron microscopy and scanning electron

diffraction analysis of selected areas, have shown that *Phase C* usually contains a small amount of nanocrystalline domains of *Phase B* with a triclinic unit cell<sup>18,19</sup>. This could be due to inhomogeneous distribution of Ba and Sr components in the mixed  $(\text{Sr}_{0.98-x}\text{Ba}_x)\text{Si}_2\text{O}_2\text{N}_2$  crystals. In  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ , the barium, strontium and europium ions are in the channels, which are formed by  $[\text{SiON}_3]$  tetrahedra and forms linear chains in the structure. In the case of *Phase A* and *Phase C* structures, cation chains are located in a small distance from each other, which is almost equal to the intra-chain distance forming a plane in the structure, while in the case of *Phase B* cation chains are separated from each other much more than the intra-chain distance. Thus the second coordination sphere around  $\text{Eu}^{2+}$  ions in *Phase A* and *Phase C* consist of  $\text{Sr}^{2+}/\text{Ba}^{2+}$  cations forming rectangle while in the case of *Phase B* the  $\text{Sr}^{2+}/\text{Ba}^{2+}$  cations form a line. Cation distribution in the second coordination sphere can result in a very different spectroscopic properties of  $\text{Eu}^{2+}$  luminescence. Poort *et al.*<sup>20</sup> have suggested that electron–lattice interaction energy, manifested by large Stokes shift between emission and absorption spectra is large when  $\text{Eu}^{2+}$  ions occupy the lattice sites that belongs to the linear cationic chain.

The high pressure study of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  doped with  $\text{Eu}^{2+}$  presented in this contribution is continuation and extension of the research work presented in ref. 18. where the relations between the luminescence properties and the content of Ba and Sr have been discussed.

It is well known that pressure is an important physical parameter that can induce the structural phase transitions<sup>21,22</sup>. X-ray diffraction study of  $(\text{Sr}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  under hydrostatic pressure has shown that in pressure range up to 96.5 kbar triclinic structure was conserved<sup>23</sup>. The main motivation on performing high hydrostatic pressure was to investigate whether high pressure influences the structural stability of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0 < x \leq 0.98$ ) to induce phase transitions. Phase transitions were identified through a comparison of the luminescence and Raman properties under pressure. High pressure, which permits us to continuously vary structural parameters, allow to answer question whether phase transitions are related to structural parameters like bond length and lattice constants. To achieve that, complementary studies of chemical pressure (through replacement of  $\text{Sr}^{2+}$  by larger  $\text{Ba}^{2+}$ ) and external high hydrostatic pressure up to 200 kbar (20 GPa) applied in diamond anvil cell (DAC) have been carried out. Finally, we have developed the phase diagram of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  which shows the relation between chemical and external pressure compression effects.

Properties of complex consisting of  $\text{Eu}^{2+}$  ions and its negatively charged coordination sphere can be described using crystal field approximation in such case high hydrostatic pressure causes the increase of the energies of the  $4f^7$ ,  $4f^65d^1$  electronic configuration with respect to the host bands energies and the increase of the  $4f^65d^1$  levels splitting<sup>24,25</sup>. The superposition of these effects are seen as a pressure-induced diminishing of the energy of luminescence related to the  $4f^65d^1 \rightarrow 4f^7$  transition. The influence of the second coordination sphere may bring about drastic changes in this effect, since it can magnify or cancel the influence of the first coordination sphere. As a result, different pressure behavior of the luminescence band related to the  $4f^65d^1 \rightarrow 4f^7$  transition of  $\text{Eu}^{2+}$  ions in different phases is expected.

The study of luminescence under high hydrostatic pressure results in better understand the relationship between pressure and crystal phases of oxynitridosilicate phosphors, and further clarify the influences of these phase transitions on photoluminescence properties, which might be general to oxynitride materials and will be useful in tuning optical and other properties that are sensitive to local coordination environments.

## Results

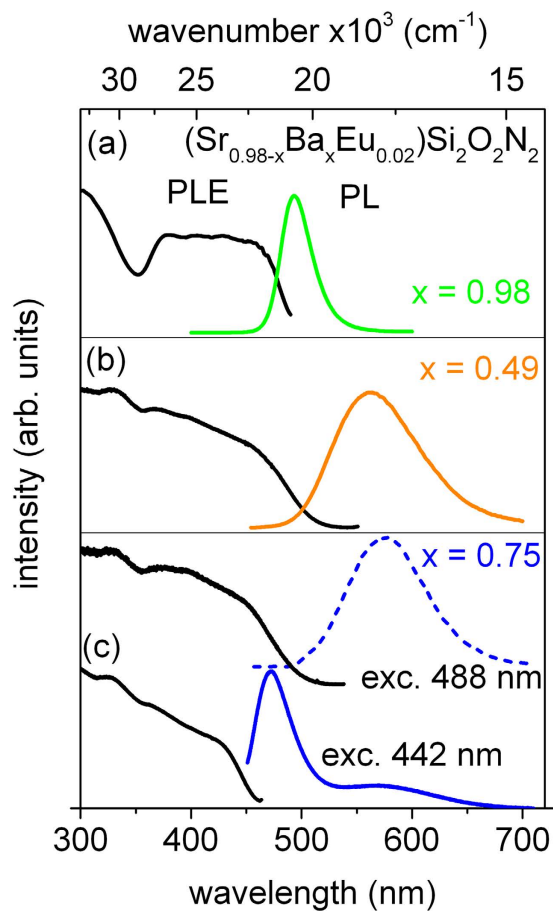

For spectroscopic studies the representatives of three different phases were selected:  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (*Phase A*; orthorhombic; *Pbcn*),  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{N}_2\text{O}_2$  (*Phase B*; triclinic; *P1*) and  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (*Phase C*; triclinic; *P1*).

Photoluminescence excitation (PLE) and photoluminescence (PL) spectra of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  system for  $x = 0.98$  (*Phase A*)  $x = 0.49$  (*Phase B*) and  $x = 0.75$  (*Phase C*) are presented in Fig. 1a–c, respectively. To interpret the spectra the first and the second coordination sphere in the vicinity of  $\text{Eu}^{2+}$  ions in different crystal phases were considered. The first and the second coordination of  $\text{Eu}^{2+}$  in  $\text{Sr}^{2+}/\text{Ba}^{2+}$  sites in *Phase A*, *B* and *C* are presented in Fig. 2a–c, respectively.

PLE spectra consist of several bands related to the parity allowed transitions from the ground state  $4f^7(^8S_{7/2})$  to excited states of the  $4f^65d^1$  electronic configuration of  $\text{Eu}^{2+}$  ions. The PL spectra consist of broad band(s) which is (are) related to the  $4f^65d^1 \rightarrow 4f^7$  (d-f) transition of  $\text{Eu}^{2+}$  ions. The maximum of luminescence band varies from blue to green spectral region, depending on the ratio of  $\text{Ba}^{2+}$  to  $\text{Sr}^{2+}$ . The PL spectrum of the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  consists of a single band peaking at 495 nm with a full width at half maximum (FWHM) equal to 32 nm (see Fig. 1a). In the orthorhombic phase (space group *Pbcn*, *Phase A*)<sup>18</sup> of  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ ,  $\text{Eu}^{2+}$  ions can occupy  $\text{Ba}^{2+}$  site which is coordinated by eight oxygen ions creating cuboid and two long ranged nitrogen ions (see Fig. 2a)<sup>13,14</sup>. The Ba–O bond lengths range from 2.74 Å to 3.10 Å and the average distance is equal to 2.89 Å whilst Ba–N distances are equal for both nitrogen and the distance is equal to 3.31 Å.

We consider this to be the first coordination sphere. The  $\text{Ba}^{2+}$  ions form linear chains in the lattice. The distance between two separate  $\text{Ba}^{2+}$  chain is almost equal to distance between  $\text{Ba}^{2+}$  ions in a given chain, thus the second coordination sphere consist of an  $\text{Ba}^{2+}$  cations forming rectangle around  $\text{Eu}^{2+}$  central ion (see Fig. 2a).

The PL spectrum of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{N}_2\text{O}_2$  is presented in Fig. 1b. The spectrum consists of a broad band with a maximum at 560 nm and FWHM equal to 80 nm. In the triclinic phase (space group *P1*, *Phase B*)<sup>12,14,16</sup> of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{N}_2\text{O}_2$  there are four different  $\text{Sr}^{2+}/\text{Ba}^{2+}$  crystallographic sites, which can be occupied by  $\text{Eu}^{2+}$  ions. These four sites are very similar, and have nearly the same surrounding. Each of them can be depicted as a distorted trigonal prism of six oxygen ions around  $\text{Sr}^{2+}/\text{Ba}^{2+}$  which is capped by one N ion (see Fig. 2b)<sup>12,16</sup>. The Sr/Ba–O bond lengths range from 2.50 Å to 3.05 Å (the average distance is equal to 2.67 Å) and Sr/Ba–N distance is equal to 2.58 Å.

**Figure 1.** PLE and PL spectra of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  samples (a)  $x=0.98$  (b)  $x=0.49$  (c)  $x=0.75$ . Emission spectra are excited at 442 nm (and additionally at 488 nm for  $x=0.75$ ). Excitation spectra were monitored at maximum of luminescence intensity.

**Figure 2.** The first and second coordination of  $\text{Eu}^{2+}$  central ions in three phases of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  samples (a)  $x=0.98$  (Phase A; orthorhombic; Pbcn), (b)  $x=0.49$  (Phase B; triclinic; P1) (c)  $x=0.75$  (Phase C; triclinic; P1).  $\text{Eu}^{2+}/\text{Sr}^{2+}/\text{Ba}^{2+}$ -ions are drawn in light grey spheres, O-ions in red spheres and N-ions in blue spheres.

The  $\text{Sr}^{2+}/\text{Ba}^{2+}$  ions in this case are in channels, which forms almost linear chains and the distance between two separate  $\text{Ba}^{2+}/\text{Sr}^{2+}$  chains are longer than between  $\text{Ba}^{2+}/\text{Sr}^{2+}$  ions in a given chain. Thus the second coordination sphere around central ions consist of two  $\text{Sr}^{2+}/\text{Ba}^{2+}$  cations forming the line (see Fig. 2b). When  $\text{Eu}^{2+}$  ion is built into this chain the attractive potential of the close positive charges orients and elongates the 5d orbital of  $\text{Eu}^{2+}$  into the chain direction partially out of the first coordination sphere<sup>20</sup>. As the result, the 5d electron is more delocalized than in the case of *Phase A*, where no preferential orientation and elongation of 5d orbital occurs. Such delocalization of the 5d<sup>1</sup> electron in  $\text{Eu}^{2+}$  is responsible for the fact that the energy of electron-lattice interaction in the excited state of  $\text{Eu}^{2+}$  is larger than in *Phase A* and results in a lower energy of the luminescence band and larger FWHM.

The PL spectra of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  obtained with different excitation wavelength are presented in Fig. 1c. Under UV to blue excitation, the emission spectrum consists of two broad bands (solid curve). The first band peaking at 470 nm with FWHM equal to 41 nm is attributed to the d-f emission of  $\text{Eu}^{2+}$  occupying  $\text{Sr}^{2+}/\text{Ba}^{2+}$  positions in *Phase C* (triclinic *P1*). In this phase there is one  $\text{Ba}^{2+}/\text{Sr}^{2+}$  site, which can be depicted as a distorted cuboid of eight  $\text{O}^{2-}$  ions (mean distance between oxygen ions and central ion is equal to 2.92 Å) and two long-ranged  $\text{N}^{3-}$  ions 3.14 Å and 3.57 Å.

It is worth noting that among these three environments of  $\text{Eu}^{2+}$  ions (*Phase A, B, C*) the average distance between the  $\text{Eu}^{2+}$  ion and nearest O/N ions (first coordination sphere) is the largest in *Phase C* and smallest in *Phase B*. Similar but smaller is in the phase A. The differences in the average distances result in the differences in the crystal field splitting of the 4f<sup>6</sup>5d electronic manifold of  $\text{Eu}^{2+}$  ion. The smallest crystal field splitting hence the maximum of  $\text{Eu}^{2+}$  luminescence has the highest energy in *Phase C*. The strong shift of  $\text{Eu}^{2+}$  luminescence into red in *Phase B* is the result of the largest crystal field splitting.

The second coordination sphere around central ions consists of the  $\text{Ba}^{2+}$  cations forming rectangle around central ion (see Fig. 2c). This situation is similar to the case of *Phase A*, and there is no preferential orientation in the space and elongation of d orbitals, thus the  $\text{Eu}^{2+}$  luminescence is observed at high energy with a small FWHM. The second band in the yellow range of the spectrum is attributed to the occurrence of a small amount of nanocrystalline domains that contains less Ba than  $x = 0.75$  (domains of *Phase B*). This could be due to inhomogeneous distribution of a Ba and Sr components in the mixed  $(\text{Sr}_{0.98-x}\text{Ba}_x)\text{Si}_2\text{O}_2\text{N}_2$  crystals.

Emission spectra related to  $\text{Eu}^{2+}$  in domains of *Phase B* were obtained when the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  was excited with wavelength 488 nm (dotted curve in Fig. 1c). This emission consists of a broad band peaked at 575 nm with FWHM equal to 83 nm. Position of the maximum of the luminescence band allows to relate this emission to the *Phase B* domains of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  with concentration  $x = 0.63$ <sup>18</sup>.

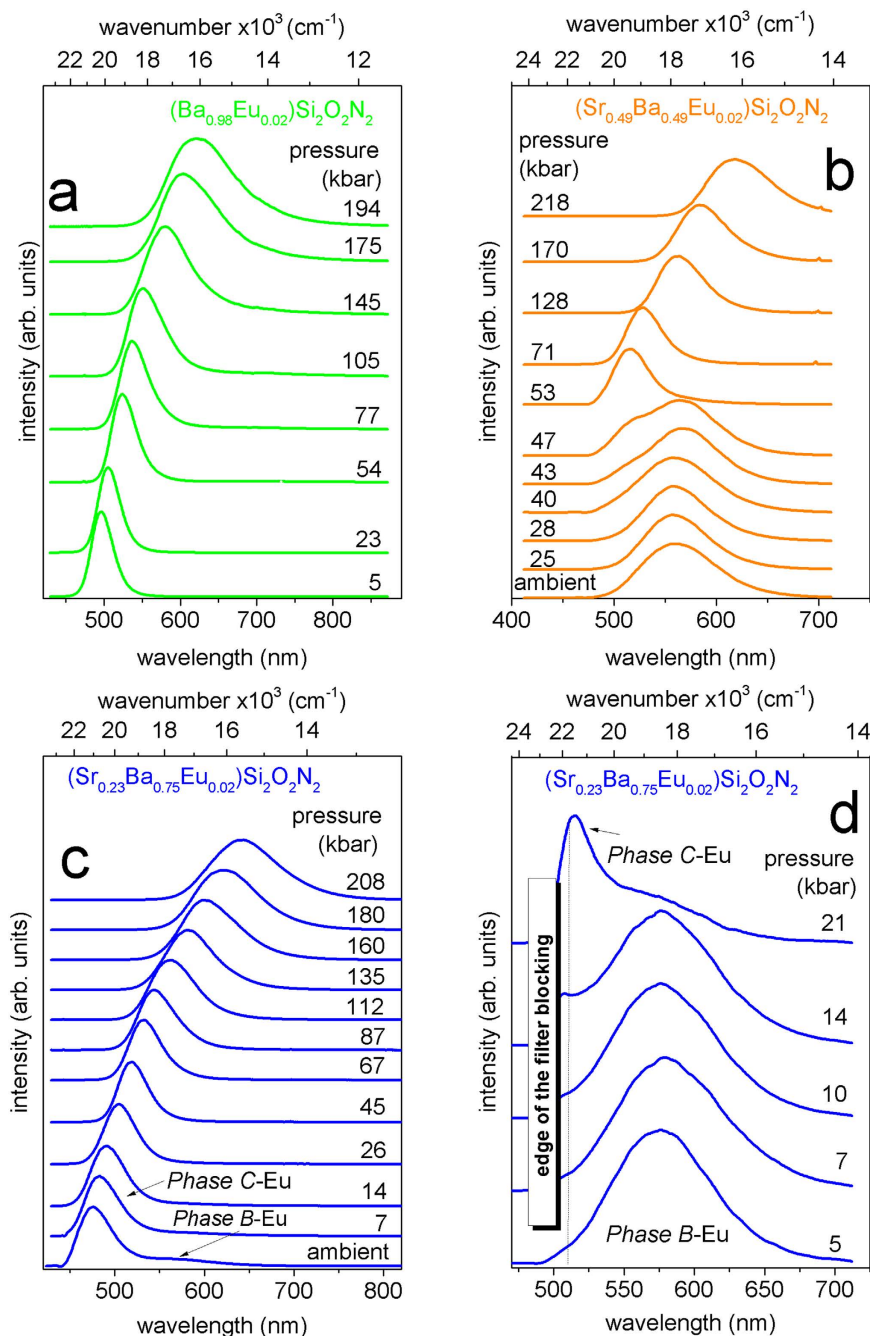

Photoluminescence spectra of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.98, 0.49, 0.75$ ) measured at different high hydrostatic pressures are presented in Fig. 3(a–d). Energies of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.98, 0.49$  and  $0.75$ ) emission maxima versus pressure are presented in Fig. 4. In Fig. 4 the green solid circles refers to the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ , the orange squares refers to the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  and solid and open blue triangles refer to the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  samples.

In the case of the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (*Phase A*) a red shift of the 4f<sup>6</sup>5d<sup>1</sup> – 4f<sup>7</sup> emission band is observed (see Fig. 3a). The energy of the emission maximum shifts linearly with increasing pressure with a rate of about  $20 \text{ cm}^{-1}/\text{kbar}$  (see Fig. 4, green circles).

Figures 3(b) and 4 (orange solid squares) present the pressure evolution of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  luminescence. Up to 40 kbar the PL spectrum with maximum at 560 nm does not change. At pressures above 40 kbar additional luminescence band with maximum at about 500 nm appears. The band with maximum at 560 nm is quenched with increasing pressure and vanishes at 50 kbar. Above 50 kbar only the band with maximum at about 500 nm is seen. Further increase of pressure up to 200 kbar causes the shift of emission maximum toward to the lower energies with rate approximately equal to  $-20 \text{ cm}^{-1}/\text{kbar}$  (see Fig. 4 orange solid squares). Such behavior of the PL of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  versus pressure can be attributed to the pressure induced structural transformation of the  $\text{Eu}^{2+}$ -ligand system. At ambient condition the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  has a triclinic  $\text{SrSi}_2\text{O}_2\text{N}_2$ -type structure (*Phase B*). The new emission signal that appears at pressure above 40 kbar can be related to beginning of a structural transformation of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . Since from 40 to 50 kbar the PL spectrum of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  consist of two bands we propose that two phases coexist in this pressure range. One notices that at 50 kbar the luminescence band of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  has maximum at the same energy as the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . Moreover, when pressure increases above 50 kbar the luminescence maximum shifts with the same rate ( $-22.8 \text{ cm}^{-1}/\text{kbar}$ —orange solid squares) as it has been observed for  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $-21.3 \text{ cm}^{-1}/\text{kbar}$ —green solid circles). This indicates that pressure-induced phase transition from triclinic  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (*Phase B*) to orthorhombic phase (*Phase A*) takes place.

The PL spectra of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  under different pressure are presented in Fig. 3(c,d). In Fig. 3(c) the 4f<sup>6</sup>5d<sup>1</sup> – 4f<sup>7</sup> $\text{Eu}^{2+}$  emission, obtained under excitation with wavelength 442 nm is presented. When pressure increases up to 20 kbar, energy of the maximum of emission band decreases (the red shift is approximately equal to  $-40 \text{ cm}^{-1}/\text{kbar}$ ). Above 20 kbar, the red shift rate diminishes and is approximately equal to  $-20 \text{ cm}^{-1}/\text{kbar}$  (see solid blue triangles in Fig. 4) which is similar to that observed for orthorhombic  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  and high pressure orthorhombic  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  structures. We propose that this change in the rate of the PL pressure shift, is the result of phase transition from triclinic (*Phase C*) to orthorhombic (*Phase A*) phase of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  system.

Figure 3(d) presents pressure evolution of the emission of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in *Phase B* domains, excited with wavelength 488 nm. It is expected that these domains would transform into *Phase A* under pressure and this actually happened (see Figs 3d and 4). Within the pressure range from ambient to 20 kbar the PL maximum does not change and the luminescence intensity gradually decrease. Above 20 kbar this luminescence is completely quenched. The phase transition in this case occurs for a lower pressure (approximately 20 kbar) than it

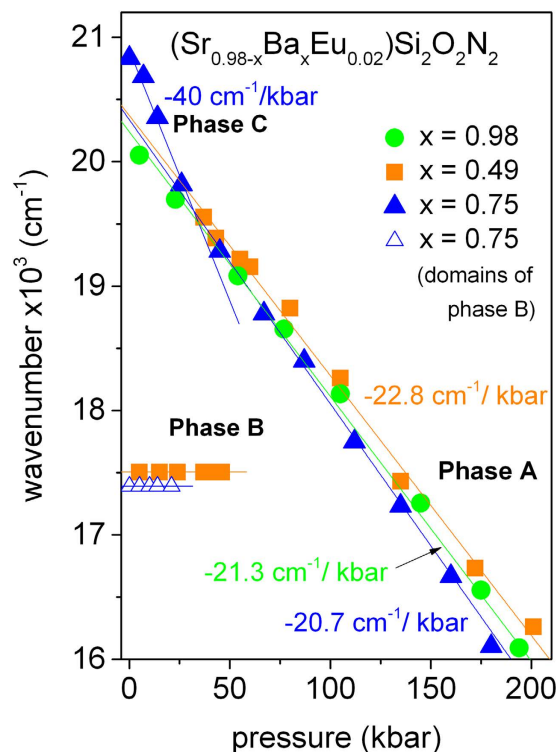

**Figure 3.** PL spectra of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  under different pressures (a)  $x = 0.98$  excited at 442 nm (d),  $x = 0.49$  excited at 442 nm, (c,d)  $x = 0.75$  excited at 442 nm and 488 nm, respectively.

is observed for  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (approximately 50 kbar) as the ratio of Ba to Sr in the domains is higher ( $x = 0.63$ ).

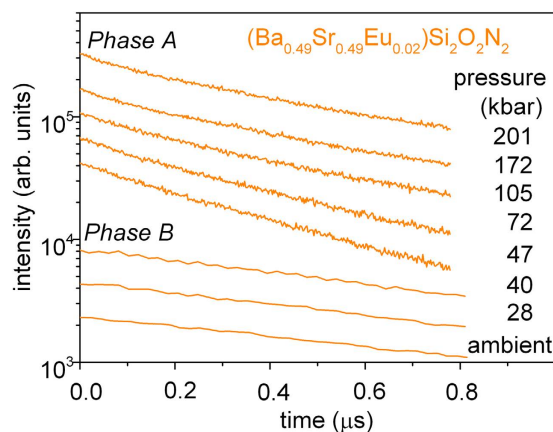

Room temperature luminescence decays of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.98$  (Phase A),  $x = 0.49$  (Phase B) and  $x = 0.75$  (Phase C and domains of Phase B) recorded at different pressures were monitored at the maximum of the  $5d^14f^6 \rightarrow 4f^7$  transition. The example of the PL decays for the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  are shown in Fig. 5. All decays related to the  $\text{Eu}^{2+}$  emission in compounds under study were close to single exponential. The decay times versus pressure for all considered samples are collected in Fig. 6. The PL decay time obtained for the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (green circles), at ambient pressure is equal to  $0.38 \mu\text{s}$  and increase gradually to  $0.54 \mu\text{s}$  at 200 kbar. In the absence of nonradiative processes this behavior can be expected because the luminescence lifetime elongates as the emission is red shifted with increasing pressure<sup>26</sup>.

The PL decay time obtained for the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (orange squares) at ambient pressure is equal to  $1.13 \mu\text{s}$ . The decay time slightly decrease with increasing pressure to  $0.89 \mu\text{s}$  at 50 kbar which is accompanied by the decrease of emission intensity and at 50 kbar luminescence with maximum at 560 nm vanishes completely.

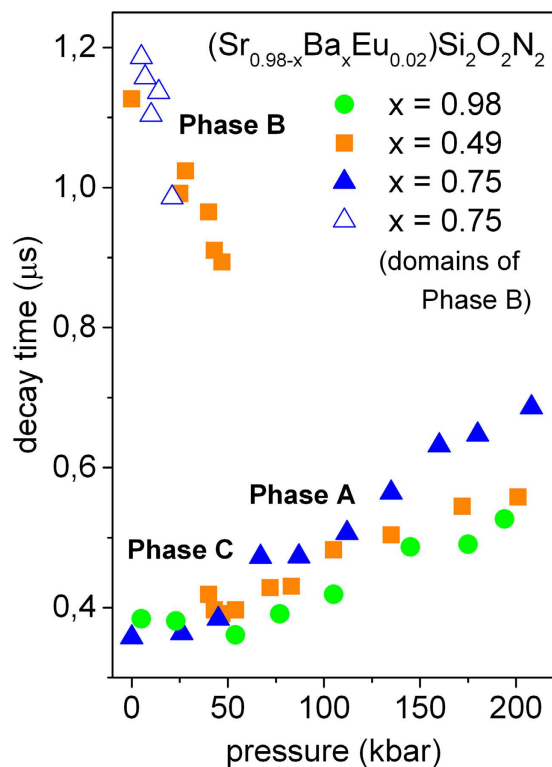

**Figure 4.** Pressure dependence of the maximum of PL spectrum  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.98$  –green solid circles,  $x = 0.49$  –orange solid squares and  $x = 0.75$  –blue solid and open triangles.

**Figure 5.** PL decays of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for different pressures collected at maximum of luminescence under excitation of 442 nm.

Across the phase transition at about 40 kbar, new luminescence band appeared (see Fig. 3b) and this emission decays with the time equal to  $0.42 \mu\text{s}$ . Increase of pressure slightly elongates the luminescence decay like it was observed for the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  sample. The pressure-dependence of the PL decay time for the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  confirms our previous consideration of the structural transformation of *Phase B* into *Phase A* induced at about 40–50 kbar. The PL decay of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (*Phase C*) monitored at maximum of luminescence is represented by closed blue solid triangles. The decay time at ambient pressure is equal to  $0.36 \mu\text{s}$ . Above 20 kbar the decay time elongates with pressure and reach the value of  $0.67 \mu\text{s}$  at 200 kbar. The same behavior is observed for the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  above 50 kbar (after phase transition) and for the  $(\text{Ba}_{0.89}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in all considered pressure. Pressure dependence of the PL decay time of the *Phase B* domains in the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  are represented by open blue triangles. At ambient pressure *Phase B* domains have a decay time equals  $1.19 \mu\text{s}$ , which is close to the value obtained for the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in *Phase B*. Pressure slightly shortens the decay time to a value of  $0.99 \mu\text{s}$  for 20 kbar which is accompanied by decrease of luminescence intensity. Above 20 kbar the luminescence from *Phase B* domains is not present in the emission spectra of the  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  system.

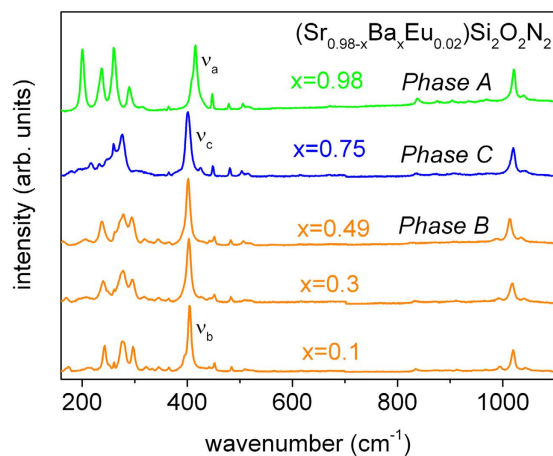

**Figure 6.** Pressure dependence of the PL decay times of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.98$  –green circles,  $x = 0.49$  –orange squares and  $x = 0.75$  –open and solid blue triangles.

One should discuss the phenomenon of the  $\text{Eu}^{2+}$  luminescence in *Phase B*. In contrast to *Phases A* and *C* the  $\text{Eu}^{2+}$  emission in *Phase B* consists of broad band characterized by FWHM equal to 83 nm, which decays with the decay time 1.2  $\mu\text{s}$ , whereas the  $\text{Eu}^{2+}$  emission in *A* and *C* phases is represented by much sharper band, characterized by FWHM equal to 41 nm decaying with the lifetime  $\sim 0.36 \mu\text{s}$ . Additionally very different pressure shifts of the  $4f^65d \rightarrow 4f^7$  luminescence of  $\text{Eu}^{2+}$  in the *Phases A* and *C* (where it is equal to  $-20 \text{ cm}^{-1}/\text{kbar}$  and  $-40 \text{ cm}^{-1}/\text{kbar}$ , respectively) and in *Phase B* (where it is equal zero) have been observed. This different pressure dependences of the emission can be attributed to different interaction of the  $\text{Eu}^{2+}$  system in the  $4f^65d^1$  state with the second coordination sphere of positive ions. In the case of  $\text{Eu}^{2+}$  in  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in *Phase B*, the 5d electron of  $\text{Eu}^{2+}$  is attracted by the positively charged chain and therefore is delocalized and can be partly located out of the first coordination sphere of negative ions. This results in large Stokes shift and FWHM of the luminescence, actually much larger than in the case of the  $4f^65d \rightarrow 4f^7$  luminescence of  $\text{Eu}^{2+}$  in  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in *Phase A* and *Phase C*.

Since pressure decrease distance between  $\text{Eu}^{2+}$  ion and ligand ions, it is expected that the pressure induces the red shift of the d-f luminescence due to the increase of crystal field splitting of 5d electronic manifold. This effect has been previously observed in many different compounds<sup>27</sup>. The first coordination sphere of the  $\text{Eu}^{2+}$  in  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  is built with negative ions having approximately cubic symmetry. These causes the splitting of the 5d orbital into doubly degenerated the lower state (e) and triply degenerated the higher state (t)<sup>28</sup>. In the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  having *Phase A* the second coordination sphere is built with four positive ions (approximately  $C_{4v}$  symmetry) which can be considered as an octahedron without vertical ions. This configuration magnifies the splitting caused by first configurational sphere and additionally splits the double degenerated the lower state (e) into the non-degenerated  $a_1$  and  $b_1$  states. As the result large pressure shift of the luminescence related to the  $4f^65d \rightarrow 4f^7$  luminescence  $\text{Eu}^{2+}$  emission in *Phases A* and *C* is observed. Due to the delocalization of the 5d electron in  $(\text{Sr}_{1-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  in *Phase B* the energy of the lowest state of the  $5d^14f^6$  electronic manifold can be not sensitive to actual positions of negative ions forming the first coordination sphere and finally does not dependent on pressure.

Raman spectroscopy has been applied to confirm structure changes of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.1$ , 0.3, 0.49, 0.75 and 0.98 and pressure-induced phase transition of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . The ambient pressure Raman spectra of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for different Ba concentrations are presented in Fig. 7. The crystal structure of oxynitridosilicates  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  are built of  $\text{SiON}_3$  tetrahedral layers with the same general topology for all samples. It is expected that internal stretching and bending vibrations of the tetrahedral  $\text{SiON}_3$  groups contribute to Raman peaks in the range  $400\text{--}1200 \text{ cm}^{-1}$  for all samples<sup>29,30</sup>. In this spectral region, the Raman spectrum of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.98$  is dominated by an intense lines with energies equal to  $415 \text{ cm}^{-1}$  (labeled  $\nu_a$ ) and  $1020 \text{ cm}^{-1}$  and for  $x \leq 0.75$ ,  $401\text{--}405 \text{ cm}^{-1}$  (labeled  $\nu_c$  and  $\nu_b$ ) and  $1020 \text{ cm}^{-1}$ . Difference between position of  $\nu_a$  with respect to  $\nu_b$  and  $\nu_c$  peaks are due to different degree of distortion of  $\text{SiON}_3$  groups. The external vibrations involving the entire  $\text{SiON}_3$  as well as their neighboring  $\text{Sr}^{2+}/\text{Ba}^{2+}$  ions

**Figure 7.** Raman spectra of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for different Ba content  $x$ .

are observed below  $400\text{ cm}^{-1}$ <sup>29,30</sup>. Here the highest intensity peaks in the spectrum of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.1$ ) are detected at  $244\text{ cm}^{-1}$ ,  $261\text{ cm}^{-1}$ ,  $278\text{ cm}^{-1}$  and  $298\text{ cm}^{-1}$ . The substitution of  $\text{Sr}^{2+}$  by  $\text{Ba}^{2+}$  up to  $x = 0.49$  causes broadening of observed peaks but the specific Raman peak pattern is preserved. For  $\text{Ba}^{2+}$  content  $x = 0.75$  and  $x = 0.98$  apparently different Raman pattern is observed below  $400\text{ cm}^{-1}$ . The highest intensity peaks in the spectrum (below  $400\text{ cm}^{-1}$ ) for  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.75$ ) are observed at  $275\text{ cm}^{-1}$  and  $260\text{ cm}^{-1}$ , whereas for  $(\text{Ba}_{0.98-x}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.98$ ) the highest intensity peaks are observed at  $201\text{ cm}^{-1}$ ,  $237\text{ cm}^{-1}$ ,  $259\text{ cm}^{-1}$  and  $289\text{ cm}^{-1}$ . Difference in position and relative intensity of Raman peaks of studied samples clearly illustrate that three different phases exist across  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  series and confirmed the previous XRD results<sup>18</sup>.

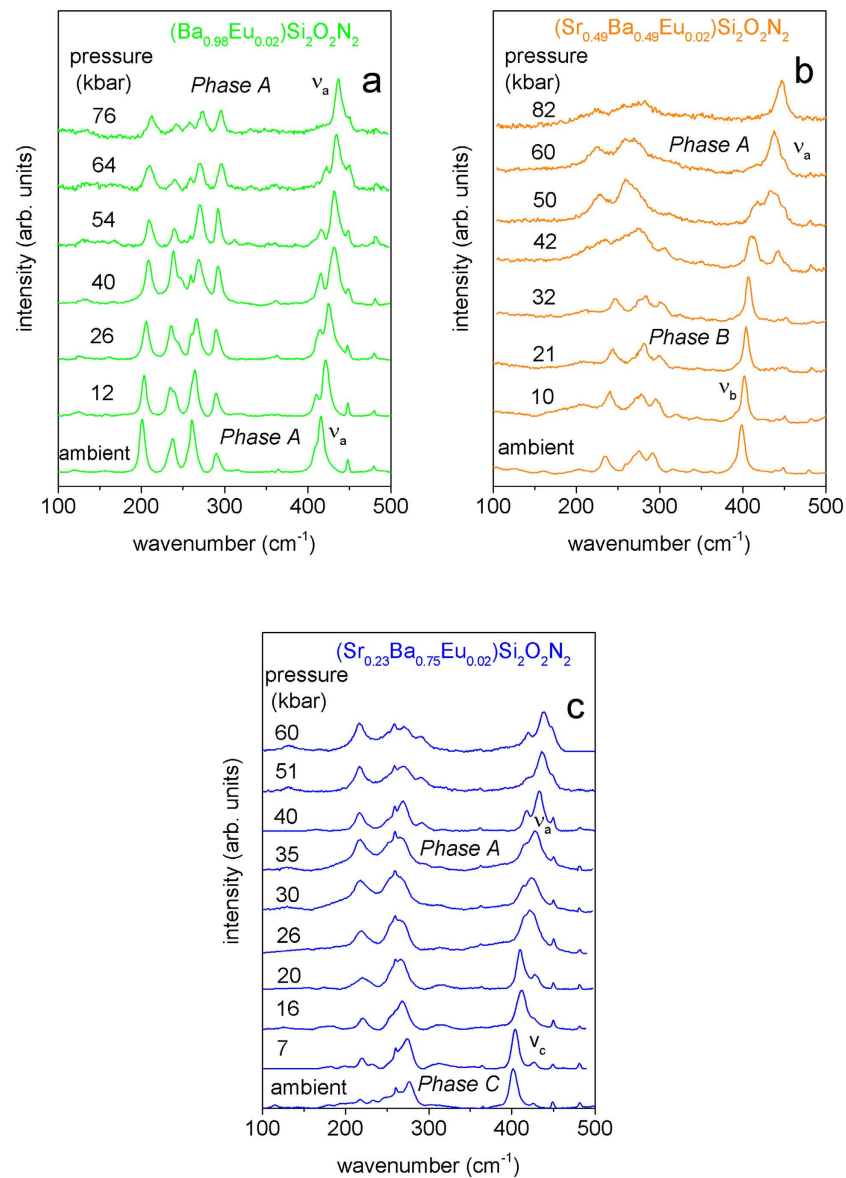

To verify our hypothesis about pressure-induced phase transformations from triclinics (*Phase B* and *C*) to orthorhombic phase (*Phase A*) Raman spectra of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for  $x = 0.49$ ,  $0.75$  and  $0.98$  have been measured at different pressures up to  $\sim 80$  kbar and the results are presented in Fig. 8a–c. It should be noted here that in our experiments the  $\text{Eu}^{2+}$  luminescence with laser beam excitation of  $632\text{ nm}$  contributes greatly to the background level causing the Raman spectra were very difficult or even impossible to measure under pressure greater than  $80$  kbar. In the case of  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  (see Fig. 8a). It is seen that due to the decrease of bonding length, energy of all Raman peaks increases with pressure. This increase is observed with a slightly different pressure rate for all lines causing that some of unresolved peaks at ambient pressure (see for example  $\nu_a$ ) start to be resolved at higher pressure, but the main Raman pattern and number of peaks does not change with pressure. These result confirms findings from luminescence studies, that the orthorhombic phase of  $(\text{Ba}_{0.89}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  is preserved in measured pressure range. Figure 8b shows high-pressure Raman spectra of  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . The most interesting effect occurs above  $32$  kbar where a significant change in the Raman lines structure is observed. Let us focus on the most intensive vibration peak  $\nu_b$  related to the internal stretching and bending vibrations of the  $\text{SiON}_3$  groups. It is seen that due to the increase of Si–O/N bonding strength energy of  $\nu_b$  increases when pressure increases. In the range of pressure between  $40$  kbar and  $50$  kbar additional peak labeled  $\nu_a$  appears and simultaneously intensity of  $\nu_b$  decreases. Above  $50$  kbar peak  $\nu_a$  remains exclusively. The  $\nu_a$  Raman line can be attributed to an orthorhombic structure of the  $(\text{Ba}_{0.98}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . The appearance of  $\nu_a$  peak at  $\sim 42$  kbar confirms the phase transition of the  $(\text{Sr}_{0.49}\text{Ba}_{0.49}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  from triclinic to orthorhombic phase. Figure 8c shows high-pressure Raman spectra of  $(\text{Sr}_{0.23}\text{Ba}_{0.75}\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  which is representative of *Phase C*. Also in this case we have observed significant changes in Raman spectra but at lower pressure of about  $26$  kbar suggesting a structural transition occurs at this point. At this pressure additional peak labeled  $\nu_a$  appears and simultaneously intensity of  $\nu_c$  decreases. Also obvious changes in Raman spectra below  $400\text{ cm}^{-1}$  are observed. Upon decompression, the luminescence and structural properties of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $x = 0.98$ ,  $0.49$  and  $0.75$ ) of these crystals returns to ambient state. It means that the high-pressure induced phase transition of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0.49$  and  $0.75$ ) is reversible.

In summary we developed the phase diagram of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  which has been shown on Fig. 9. The dotted lines represent the phase boundaries between different phases in the pressure and Ba content space. Two points corresponding to pressures of phase transitions for  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$   $x = 0.3$  and  $x = 0.1$  (black squares in Fig. 9) were obtained at high pressure luminescence experiments, however the respective luminescence and Raman spectra are not presented in this contribution. The phase diagram shows that pressure in which phase transition between *Phase B* and *A* occurs decreases linearly with increasing Ba concentration in  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ . The boundary between *Phase B* and *A* is indicated by dotted red line. For concentration range  $0.65 < x < 0.78$  and pressure lower than  $20$  kbar the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  system exists in *Phase C*. The boundary between *Phase B* and *C* is indicated by dotted black line.

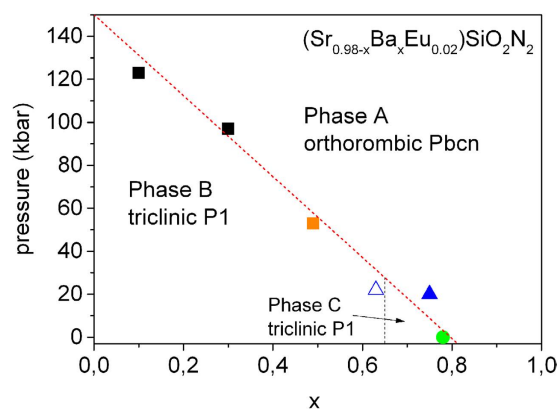

## Methods

**Chemicals and Materials.**  $\text{SrCO}_3$  ( $\geq 99.9\%$ ),  $\text{SiO}_2$  ( $\geq 99.995\%$ ),  $\text{Si}_3\text{N}_4$  ( $\geq 99.9\%$ ), and  $\text{Eu}_2\text{O}_3$  ( $\geq 99.99\%$ ) were purchased from Aldrich Corporation.  $\text{BaCO}_3$  ( $\geq 99.9\%$ ) was purchased from J.T. Baker Corporation. All of the

**Figure 8.** Raman spectra of the  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  for (a)  $x = 0.98$  (b)  $x = 0.49$  and (c)  $x = 0.75$  at different pressures.

**Figure 9.** Phase diagram of  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$ .

initial chemicals were used without further purification. Aluminum oxide crucibles and cylindrical molybdenum crucibles (20 mm × 50 mm) were used in the sintering process of the samples.

**Synthesis.** A series of oxonitridosilicate compounds,  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0.1 \leq x \leq 0.98$ ), was prepared using two-step solid-state reaction processes. Nonstoichiometric amounts of  $\text{SrCO}_3$ ,  $\text{BaCO}_3$ ,  $\text{SiO}_2$ , and  $\text{Eu}_2\text{O}_3$  powders, in which the molar ratio of (Sr, Ba)/Si = 0.8 were ground in an agate mortar for 30 min to form a homogeneous mixture. The mixture was then placed in aluminum oxide crucible and fired at 1250 to 1350 °C for 6 h under flowing 95%  $\text{N}_2$ –5%  $\text{H}_2$  atmosphere in a horizontal tube furnace. The sintered products were ground, yielding crystalline powder  $(\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02})\text{Si}_2\text{O}_2\text{N}_2$  ( $0.1 \leq x \leq 0.98$ ). The crystalline powder was mixed with stoichiometric amounts of  $\text{Si}_3\text{N}_4$  and reground for 30 min in an agate mortar. After forming a homogeneous mixture, the mixture was loaded into a cylindrical molybdenum crucible with a screw-cap and fired again at 1500 to 1550 °C for 6 h under flowing 95%  $\text{N}_2$ –5%  $\text{H}_2$  atmosphere in the horizontal tube furnace. The second sintered products were ground again, yielding the resulting phosphor powder. The details of samples preparation and ambient pressure structural characterization were presented and discussed in paper<sup>18</sup>.

**Spectroscopic characterization.** Raman spectra were recorded at room temperature and ambient pressure on a Horiba JobinYvon Lab Ram Aramis spectrometer with a He-Ne laser providing excitation light at 633 nm with the 1200 l/mm grating.

Photoluminescence excitation spectra were acquired using a FluoroMax-4P TCSPC spectrofluorometer produced by Horiba, containing Czerny-Turner monochromators for excitation and emission. An excitation source in this system was a 150-W ozone-free Xenon lamp. Fluorescence intensity was measured using a R928 Side-on photomultiplier. Steady state luminescence spectra were excited with He-Cd laser with the wavelength of 442 nm. The photoluminescence spectra were recorded on a SR-750-D1 luminescence spectrometer with an Andor CCD camera DU420A-OE type, which can detect signal on large wavelength range 250–1000 nm with an accuracy of 0.5 nm. The spectra were corrected for instrumental spectral response using a standard lamp.

The experimental setup for luminescence kinetics consists of a PL 2143 A/SS laser as the excitation source and a PG 401/SH parametric optical generator. This system can generate 30 ps laser pulses, with the frequency of 10 Hz with wavelengths ranging from 220 to 2200 nm. The emission signal was analyzed by a Bruker Optics 2501S spectrometer and the Hamamatsu Streak Camera model C4334-01 with a final spectral resolution 0.47 nm. Luminescence decays were obtained by the integration of streak camera images over the wavelength intervals. Details of the experimental setup are described in the paper<sup>31</sup>. High hydrostatic pressure was applied in a Merrill Bassett type DAC<sup>32</sup>. Polydimethylsiloxane oil was used as the pressure-transmitting medium, and pressure was measured by the shift of the  $R_1$  luminescence line of ruby.

## Acknowledgements

This study has been supported by the National Centre for Research and Development (projects: NOPLID, PL-TWII/8/2015 and TAZOLED, PBS3/A5/48/2015). R.S.L. would like to thank the Ministry of Science and Technology of Taiwan (contract numbers MOST 104-2113-M-002-012-MY3 and 104-2923-M-002-007-MY3). G.L. thanks the National Natural Science Foundation of China (Grant No. NSFC 21301162) for financially supporting this research. The contribution of S. M. was supported by the grant “Iuventus Plus” 0271/IP3/2015/73 from the Ministry of Science and Higher Education.

## Author Contributions

A.L. and S.M. conceived and perform experiments. A.L. was primarily responsible for the experiments. R.S.L. and G.L. synthesized the  $\text{Sr}_{0.98-x}\text{Ba}_x\text{Eu}_{0.02}\text{Si}_2\text{O}_2\text{N}_2$  ( $0 \leq x \leq 0.98$ ) samples. M.G., A.L. and S.M. interpreted the spectroscopic data. A.L. wrote the main manuscript text, M.G. and S.M. edited the manuscript. All the authors discussed the results and reviewed the manuscript.
