

Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.

## Review

# Epidemiology, clinical ramifications, and cellular pathogenesis of COVID-19 mRNA-vaccination-induced adverse cardiovascular outcomes: A state-of-the-heart review

## ABSTRACT

The coronavirus disease 2019 (COVID-19) has overwhelming healthcare systems globally. To date, a myriad of therapeutic regimens has been employed in an attempt to curb the ramifications of a severe COVID-19 infection. Amidst the ongoing pandemic, the advent and efficacious uptake of COVID-19 vaccination has significantly reduced disease-related hospitalizations and mortality. Nevertheless, many side-effects are being reported after COVID-19 vaccinations and myocarditis is the most commonly reported sequelae post vaccination. Majority of these diseases are associated with COVID-19 mRNA vaccines. Various studies have established a temporal relationship between these complications, yet the causality and the underlying pathogenesis remain hypothetical. In this review, we aim to critically appraise the available literature regarding the cardiovascular side effects of the various mRNA vaccines and the associated pathophysiology.

## 1. Introduction

The burden that coronavirus disease 2019 (COVID-19) has forced upon global healthcare systems has necessitated concerted efforts towards global immunization programs. As of March 2022, 31 million COVID-19 vaccines have been administered, with 54% of the global population having received at least one dose of a COVID-19 vaccine [1].

While studies have reported strong evidence of immunity after a single dose of a COVID-19 vaccine, vaccination efficacy dramatically increases after two doses, specifically for the alpha and the delta variants [2,3]. Rare complications of COVID-19 mRNA vaccinations have included several cardiovascular outcomes such as: myocarditis, pericarditis, perimyocarditis, myocardial infarctions (MI), coronary thrombosis, and stress-induced cardiomyopathy (Takotsubo cardiomyopathy) [3].

Various studies have established a temporal relationship between vaccination and cardiovascular complications; nevertheless, causality remains largely inconclusive.

Myocarditis has been the predominant cardiovascular complication post-COVID-19 vaccination [4]. However, this is not the only instance of post-vaccine myocarditis historically, as myocarditis cases have been associated with other vaccinations as well [4]. The Center for Disease Control and Prevention (CDC) and the U.S. Federal Drug Administration (FDA) have been monitoring vaccine safety profile and the data surrounding post-vaccination complications, common or rare, via a plethora of vaccine safety monitoring systems: the Vaccine Adverse Effect Reporting System (VAERS), Vaccine Safety Datalink, V-safe, and the National Healthcare Safety Network. To date, the CDC has confirmed a total of 2337 reports of myocarditis in VAERS for all vaccines (1990 - November 11, 2021), 1969 of which were in people aged 30 and younger who received COVID-19 mRNA vaccines, which include the Pfizer-BioNTech and Moderna vaccines [5,6]. Following investigation of these reports, the CDC and FDA confirmed that 1005 cases met the criteria for myocarditis, pericarditis, or myopericarditis [5].

The risk of thrombotic events related to COVID-19 vaccines has been a major concern since reports have surfaced from the U.S., Singapore, India, and Europe. Although the data is limited, studies have already been conducted to differentiate clinical presentation of MI from myocarditis post-COVID-19 vaccinations. In summary, those with post-vaccination MI presented at around 24 h post-vaccination, much earlier than myocarditis at 72 h [7-10]. More importantly, most developed MI

symptoms after the first dose [9,10]. A potential mechanism for post-vaccination MI could be Kounis syndrome, an allergic hypersensitivity reaction to potentially immunogenic components found within vaccines [9,11]. The vast spectrum of cardiovascular complications reportedly associated with COVID-19 mRNA vaccinations is delineated by Fig. 1.

## 2. Methods

Using the digital databases (PubMed/MEDLINE, CINAHL, and Web of Science) to search for relevant material, a scoping review was conducted by two authors (T.A., T.K.) and articles containing cardiovascular complications after COVID-19 vaccine were incorporated in this review in a narrative style. The literature search was done for articles published between 2020 and 2022. In our search, we used the terms(s): “cardiovascular sequelae” OR “cardiovascular complications” OR “cardiovascular ramifications” OR “myocardial infarction” OR “heart failure” OR “Takotsubo cardiomyopathy” OR “myocarditis” OR “pericarditis” AND “COVID-19” OR “COVID-19 vaccine” OR “COVID-19 vaccination programs”.

## 3. Main text

### 3.1. Pathophysiology

Primary infection with severe acute respiratory syndrome

Fig. 1. The various cardiovascular complications that have been reported post-COVID-19 mRNA vaccination if.

coronavirus 2 (SARS-CoV-2) occurs when the virus' surface spike S glycoprotein binds to angiotensin-converting enzyme 2 (ACE2), allowing it to enter the cell [12,13]. ACE2 is ubiquitous throughout the body on the apical surface of epithelial cells, which likely explains the sequelae of adverse effects reportedly caused by infection [12]. Interestingly, with higher concentrations of ACE2 in the lung and heart, this potentially accounts for the pulmonary and cardiac damage that typifies a severe systemic COVID-19 infection [12].

While all the different cardiovascular complications have their own pathophysiological pathways, the COVID-19 mRNA vaccines could result in these outcomes through similar mechanisms. For instance, recent studies have implicated vaccines using a nucleoside-modified mRNA that encodes the viral membrane S glycoprotein of SARS-CoV-2. The vaccines instigate the production of antibodies that target the spike S protein, preventing binding to ACE2, thus conferring both cellular and humoral immunity [14,15]. The exosomes containing the spike proteins were also found to stimulate splenic lymphocytes to secrete interferon (IFN)- $\gamma$  and tumor necrosis factor (TNF)- $\alpha$ , amplifying the host inflammatory cell response system and instigating a cascade of immunological responses that could affect various organ systems, including the heart [15].

The immunological response induced by the vaccines could explain the inflammatory processes of myocarditis, pericarditis, and perimyocarditis. As briefly mentioned earlier, MI induced by the vaccines could be attributed to Kounis syndrome, which is largely explained by components within the vaccines known as excipients [11]. Excipients are pharmaceutical substances found alongside the active substances in a vaccine. In this case, the COVID-19 vaccine excipients are speculated

to be potentially eliciting hypersensitivity reactions amongst some recipients [11]. Different excipients are noted in various vaccine formulations; polyethylene glycol (Pfizer-BioNTech vaccine); polyethylene glycol and tromethamine/trometamol (Moderna vaccine); polysorbate 80 (Johnson & Johnson vaccine); polysorbate 80 and disodium ethylenediaminetetraacetic acid dihydrate (Sputnik V vaccine); and disodium hydrogen phosphate, sodium dihydrogen phosphate monohydrate, and sodium chloride (Sinovac-Coronavac vaccine) [11]. An IgE-mediated hypersensitivity reaction concurrent with an acute coronary syndrome (ACS) or MI is termed Kounis syndrome [16]. This syndrome is accompanied by clinical and laboratory evidence of MI whose more predominant etiologies have been excluded and instead attributed to a hypersensitivity reaction characterized by release of inflammatory mediators such as histamine, neutral proteases (tryptase, chymase, and cathepsin-D), arachidonic acid metabolites, platelet-activating factor (PAF), cytokines, and chemokines released during mast-cell degranulation and by immune cells such as T-cells, B-cells, plasma cells, and macrophages [11,16,17]. The mechanism of action of COVID-19 mRNA vaccines is elucidated in Fig. 2.

In addition to precipitating ischemic events, there have been reports of broken hearts. A recent case of post-COVID-19 vaccination Takotsubo syndrome was diagnosed and reported [18,19]. Takotsubo syndrome has been described to be primarily attributed to an identifiable physical or emotional stressor, presents similarly to ACS, and most commonly affects post-menopausal women. It is a result of myocardial wall motion abnormalities in a distribution that is covered by a single coronary artery and nearly always presents with left ventricular wall dysfunction [19–21]. Its pathophysiology is predominated by

### How the COVID-19 RNA-based Vaccine Works

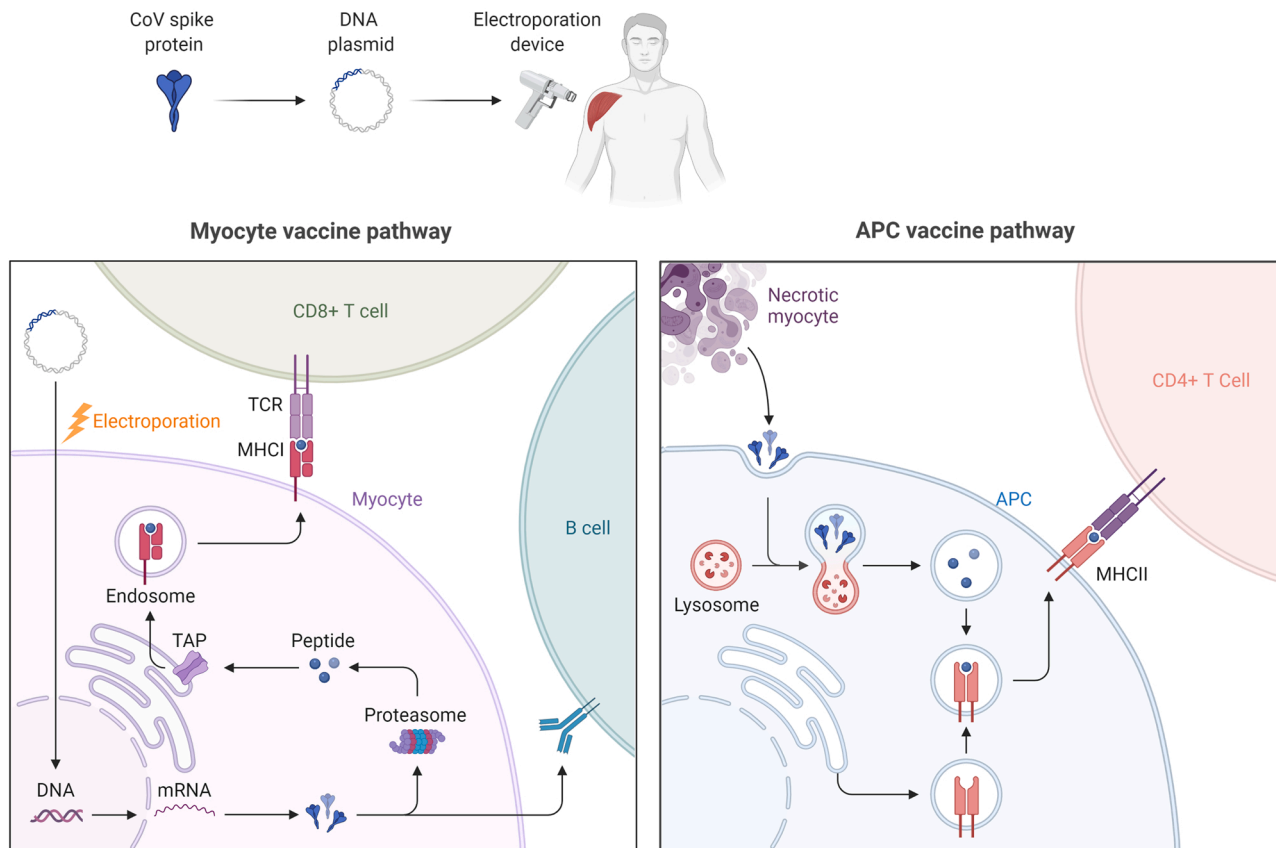

Fig. 2. The mechanism of action of COVID-19 mRNA vaccines. TCR: T-cell receptor; MHC-I: major histocompatibility complex I; TAP: transporter associated with antigen processing; MHC-II: major histocompatibility complex II; APC: antigen presenting cell.

catecholamine-mediated dysfunction and its pathogenesis post-COVID-19 vaccination is currently hypothesized to be mediated by the hypersensitivity response seen in Kounis syndrome [19].

### 3.2. Discussion

The current review aims to consolidate the data surrounding the various adverse cardiovascular events—myocarditis, perimyocarditis, pericarditis, MI, coronary thrombosis, or Takotsubo syndrome—associated with COVID-19 mRNA vaccinations (see Tables 1, 2, 3). The mean age of the participants hovered at  $56 \pm 8.7$  years, with a standard deviation (SD) of 8.4 years. There was a slight male preponderance, with 68.4% males and 31.6% females. More notably, females with any reported adverse cardiovascular event post-vaccination were, on average, older than their male counterparts (62.3 years vs 58.8 years, SD: 8.2 years, 95% confidence interval [CI]: 52.7–70.3 years,  $P < 0.05$ ).

### 3.3. Myocarditis

We included a total of 7 studies (6 case series and 1 case report) between August and November 3rd, 2021: a total of 102 cases of myocarditis post-mRNA vaccination (Table 1). The vaccinations received in the studies were as follows: 57 received the Pfizer BioNTech vaccine, 44 received Moderna, and 1 Comirnaty. Most cases were male, including the single case report, with an age range of 19–71 years old. The most common comorbidities were hypertension, smoking, and a previous history of coronary artery disease, all of which demonstrated a worse prognosis. Interestingly, patients with comorbidities, specifically hypertension and active smoking, exhibited significantly lower antibody titers following COVID-19 vaccination, which could contribute to an increased likelihood of post-vaccine complications [22]. Another study sheds further light by promoting smoking cessation prior to vaccination to ameliorate the efficacy of the BioNTech Pfizer vaccine [23].

Of the 102 cases with myocarditis, four were PCR-positive after vaccination. One study, pooling cases of myocarditis from the USA, Israel, Singapore, and a few other countries, demonstrated that 83% of the patients developed myocarditis symptoms only after the second vaccine dose [9]. Additionally, a retrospective case series analyzing data from the Mayo Clinic COVID-19 Vaccine Registry elucidated that all seven cases occurred after the second dose [7]. Other studies that have reported myocarditis symptoms occurring post-second dose of COVID-19 mRNA vaccines reported rates hovering between 40% and 100%. Among the included studies, the median time between vaccination and onset of symptoms was 1–3 days [24]. However, one study reported a mean time of onset of 15.4 days, with a range of 3–28 days [24]. The study included case reports from Switzerland using the Regional Pharmacovigilance Center (RPVC) internal database for cases of myocarditis, perimyocarditis, and pericarditis temporally related to COVID-19 mRNA vaccination [24].

Most cases of myocarditis post-vaccination presented with elevated cardiac troponin levels along with simultaneous elevations in C-reactive protein (CRP), brain natriuretic peptide (BNP) or N-terminal pro-hormone BNP (NT-proBNP) [7,9,24]. Interestingly, abnormal electrocardiogram findings were seen in a few patients. Fourteen myocarditis cases presented with a left ventricular ejection fraction (LVEF) of  $< 50\%$  [7–10, 25, 26]. Abnormal cardiac magnetic resonance imaging (MRI) with late gadolinium enhancement and edema were observed in 51 cases [7,9,24–27]. Late gadolinium enhancement was found in 41% of the patients in the subepicardial layer, 14% in the mid-myocardial layer, and 24% in both layers [9]. The same study found edema in 21% of cases within the subepicardial layer, 17% within the mid-myocardial layer, and 24% within both layers [9]. These findings further substantiate the presence of epicardial and myocardial inflammation in the aftermath of vaccination.

Almost all of the cases experienced a prompt recovery, with no residual cardiac dysfunction. However, in one study, seven patients

continued to experience chest discomfort [25]. While their follow-up is ongoing, median length of stay for all myocarditis cases was around 2–3 days with a range of 2–10 days [25]. Treatment of myocarditis cases amongst the studies included non-steroidal anti-inflammatory drugs (NSAIDs), colchicine, aspirin and steroids [25–27]. Beta blockers and ACE inhibitors were administered in some cases for left ventricular dysfunction as a cardioprotective therapy to prevent positive remodeling of the heart [7,24].

As of March 2022, the CDC reported an incidence of 4.8 cases of myocarditis per one million post-COVID-19 mRNA vaccines, with a predominance in young males [27]. The curtailed duration between COVID-19 vaccination and symptom onset is supplanted by the elevated incidence of myocarditis [27]. Notably, many studies have acknowledged limitations in these statistics, hypothesizing missed cases of post-vaccine myocarditis that would underestimate the reported incidence [28].

The incidence of myocarditis following the mRNA vaccines was higher after the second dose, especially in adolescent and young adult males within a week of vaccination [7]. The CDC collected this using data from the U.S.A database of healthcare encounters consisting of more than 900 hospitals between March 2020 and March 2022, revealing that patients infected with COVID-19 had 15.7 times the risk of myocarditis compared to noninfected patients [8]. The risk ratio varied across age (7.0 for aged 16–39 and  $>30.0$  for those  $< 16$  and  $> 75$  years old) and gender (13.8 for males, 17.8 for females) [8]. In another study from Israel, the risk ratio of myocarditis associated with mRNA vaccination and COVID-19 infection were compared (3.24 vs 18.28, respectively), showing that the risk of myocarditis is higher with infection than vaccination [8]. In regards to prognosis in this cohort, no long-term data is yet available.

### 3.4. Pericarditis

Cases of post-vaccination pericarditis were reported in studies from Switzerland and the United States, both of which compared the incidence with that of post-COVID-19 myocarditis [24,27]. A total of 40 pericarditis cases were recorded, with 75% males and a median age of 59–60 years old. While pericarditis presents similarly to myocarditis, pericarditis had a higher incidence in men with old age. Hypertension, diabetes mellitus and a previous history of coronary artery disease were the top three comorbidities.

The mean time from vaccination to onset of symptoms was 6.5 and 20 days [24,27]. It can be explained by difficulty in diagnosis of pericarditis due to less specific symptoms. In the Switzerland study, three cases were reported, with one presenting with unclear symptoms and vague diagnostic criteria score due to self-reporting [24]. This less-than-optimal clinical evaluation could be attributed to recall bias, which would contribute to limitations within the studies and lead to difficulty in evaluating temporality between the vaccine and its complications.

In the United States, 59.5% of pericarditis occurred after the second dose of the vaccine [27]. Three patients had an LVEF of  $< 50\%$ , increased troponin levels, and abnormal ECGs. Length of hospitalization ranged from 0 to 11 days. Treatment included a regimen of NSAIDs, colchicine, and steroids. However, complete resolution of symptoms was reported in only 18.9% of pericarditis cases [27].

### 3.5. Perimyocarditis

In a study, cases of perimyocarditis were identified and reported in association with the COVID-19 vaccines [24]. Data from a regional pharmacovigilance center in Switzerland included perimyocarditis diagnosed in line with the diagnostic criteria of the European Society of Cardiology [24]. Nine cases of perimyocarditis were reported with a median age of 57 years (range 17–88). Seven of the cases were males (78%) with a median age of 23 years (range 17–86) [24]. Six patients

(67%) received the Moderna vaccine, and three received Comirnaty [24]. Hypertension was reported in three patients (33%) and a previous history of CAD in two (22%). The mean time from vaccination to symptom onset was 4.7 days, with seven (78%) cases presenting after second dose [24]. Five patients (56%) presented with chest pain and two (22%) presented with nonspecific symptoms such as myalgia, fever, and other flu-like symptoms [24]. Abnormal troponin levels were observed in eight patients (89%), significant ECG findings in seven (77%), and noteworthy MRI findings in six (67%). Notably, symptoms fully resolved in only three patients (33%), among which the median length of stay was 6 days. The treatment regimen for these cases included an ACE inhibitor (administered to 4 patients) or a  $\beta$ -blocker (4 patients), followed by combination therapy with an ACE inhibitor and  $\beta$ -blocker or ibuprofen as anti-inflammatory therapy [24].

### 3.6. Myocardial infarction

A total of two case series with a total of 37 cases documenting cases of MI post-COVID-19 mRNA vaccination were studied as demonstrated in Table 3 [9,10]. Males were predominantly affected making up 78% of cases with a mean age of 55 years in one study and 65 in the other, interestingly this gender distribution was noted to be similar to the demographic most vulnerable to COVID-induced myocarditis [9,10]. Comorbidities found within the two studies included hypertension (62%), hyperlipidemia (57%), diabetes mellitus (51%), and active smoking (35%), all amongst the most significant risk factors for the complication of MI [9,10].

One of the studies pooled data from a retrospective cohort of cases of myocarditis and MI found in patients post-COVID-19 mRNA vaccination

in Singapore, and included these cases in a systematic review of similar cases from the USA, Israel, India, and other countries [9]. The median time noted between vaccination and onset of symptoms was approximately 1–2 days, with 33% of documented cases occurring post-second vaccination in one of the studies alluding to the differentiation of MI cases post vaccination occurring post first dose of the vaccine in comparison to myocarditis cases occurring more commonly post second dose of the vaccine [9]. Troponin levels were elevated in most cases, with ST-elevations found in 57% of patients in one of the studies [9]. The ST elevations were noted in anterior leads in 20% of cases, lateral leads in 6%, and inferior leads in 20%. Mean LVEF was 50% (range 40–55%), with 89% presenting with regional wall motion abnormalities on transthoracic echocardiogram (TTE) [9]. Within the same study, 66% of cases received culprit-vessel percutaneous coronary intervention (PCI): 37% left anterior descending (LAD) artery, 20% right coronary artery (RCA), 5% left circumflex (LCX) artery, and 5% other vessels [9,10].

The patients in the retrospective cohort of 35 patients were discharged on NSAIDs, colchicine, direct oral anticoagulants, β blockers, and statins, which resulted in a prompt abatement of their clinical symptoms [9]. Effective treatment with the aforementioned regimen lends further evidence to Kounis syndrome as a plausible pathophysiological explanation for the observed inflammatory phenomenon [14]. The other study reported two patients that underwent PCI to the LCX [10]. Both patients remained symptom free upon discharge and the median hospital stay was 4.5 days [10].

One hypothesis for the development of MI post-COVID-19 vaccine states that vaccines induce an autoimmune reaction response against platelets, a clinically similar phenomenon to autoimmune heparin induced thrombocytopenia. [29,30] Other studies have postulated that the stress and emotional turmoil that can accompany receipt of the COVID-19 vaccine amongst adults could lead to a demand-ischemia,

resulting in the unduly cardiac events amongst the recipients [9,31]. While the pathogenesis of MI post-COVID-19 mRNA vaccination remains elusive, Kounis syndrome is hypothesized to be a contributing factor or even etiology [9,10,14]. Older patients with underlying comorbidities such as hypertension and a previous history of CAD are more vulnerable to high stressors, and this could explain the cases of MI post-vaccination [31]. Note that these theories are different from those of myocarditis induced by COVID-19 vaccines, which were mostly attributed to non-inflammatory responses between vaccine and cardiac cell proteins [32].

A recent paper reported the case of a 86-year-old male who collapsed within 30 min after receiving the vaccination, with ECG showing ST-elevations in the inferior wall. Investigations revealed a triple coronary artery thrombosis after the first dose of the Pfizer–BioNTech vaccine, which was soon followed by hemodynamic instability [18]. Coronary angiography showed distal blockage in the left anterior descending artery, the first diagonal branch, and right coronary artery [18]. The patient was treated with primary percutaneous coronary intervention of the right coronary artery with aspiration thrombectomy, coronary balloon angioplasty, and administration of an eptifibatide, glycoprotein IIb/IIIa receptor inhibitor [18]. The patient remained hospitalized for three days and expired shortly thereafter [18]. It is of significance to note that the patient in the study had a previous history of prostate cancer for which he received treatment in 2006 through surgical resection and radiotherapy [18]. At the time of vaccination, he was on an androgen receptor inhibitor, and his medical history included paroxysmal atrial fibrillation for which he was taking apixaban twice daily [18]. In this context, a concoction of risk factors could have precipitated his clinical deterioration, contributing to a hypercoagulable state and thus leading to coronary thrombosis. Nevertheless, this would not explain the acute presentation post-vaccination. While not much can

be ascertained from a single case report, the curtailed intervening period between vaccination and onset of symptoms alludes to a link between the two, with Kounis syndrome remaining the predominant unifying theory for the pathogenesis at hand.

### 3.7. Takotsubo syndrome

Many cases of Takotsubo cardiomyopathy have been reported in association with COVID-19 infection [21]. Yet perhaps more interesting is that, since the commencement of COVID-19 vaccination regimens, there has been an increasing incidence of Takotsubo syndrome. A recent study reported the case of a 73-year-old woman with a history of chronic kidney disease (CKD) and hypertension who was admitted 17 h after Moderna's COVID-19 vaccination on suspicion of non-ST elevation myocardial infarction: a troponin of 0.22 ng/mL, creatinine 2.0 mg/dL, BNP > 70,000 pg/mL, procalcitonin 0.61 ug/L, no signs of infection, and ECG findings indicative of inferolateral ischemia and poor R wave progression [19]. TTE demonstrated LV apical ballooning, an EF of 20%, with mild mitral regurgitation, and severe right ventricular dysfunction with functional tricuspid regurgitation [19]. She was diagnosed with Takotsubo syndrome and was subsequently treated for acute heart failure [19,20]. Repeat TTE at three days showed marked improvement in her biventricular function and an EF of 35–40%, and by discharge on day 8 the heart failure had resolved.

While the ACE2 receptor has been implicated in the pathogenesis of COVID-19-induced myocardial injury leading to Takotsubo syndrome, the mechanism underlying the vaccine-induced entity of Takotsubo syndrome is not expected to herald comparable levels of cardiac injury [19]. Rather than direct damage to the heart as in infection, it was postulated that the vaccine may stimulate a systemic inflammatory response that merely sensitizes patients to catecholaminergic effects, resulting in an imbalance between sympathetic and parasympathetic drives that manifests as Takotsubo cardiomyopathy [19,21,33,34]. Furthermore, it has been postulated that the overwhelming emotional turmoil and stress fomented by the uptake of COVID-19 vaccination can herald even greater catecholamine release, which can precipitate the myocardial stunning that is observed in Takotsubo cardiomyopathy.

## 4. Summary

To summarize, several studies reporting cases of cardiovascular side effects secondary to mRNA COVID-19 vaccines have been discussed. These include myocarditis, perimyocarditis, pericarditis, MIs, and Takotsubo syndrome [21–32]. Most pertinently, the time between vaccination and the onset of symptoms varied between complications. The reported cases shared certain predisposing risk factors, such as hypertension, active smoking and a previous history of CAD [14–21]. The reported cases were mainly males with age variation. Notably, myocarditis predominantly affected younger males while pericarditis was observed in older males [24,27]. While myocarditis is the highest reported cardiovascular ramification, other serious complications are also being increasingly reported [3–12, 27, 31–33]. Nevertheless, the strength of association between the mRNA COVID-19 vaccines and cardiovascular complications is temporal, and any causality or underlying pathogenesis remain unclear and the subject of a pathophysiological conundrum.

## 5. Future perspectives

This review incorporated numerous studies reporting cardiovascular sequelae of COVID-19 mRNA vaccines. Although post-vaccination myocarditis is mild and self-resolving, other serious complications such as thrombosis can incur adverse outcomes in the patients. The aim should be close monitoring for those who present with similar symptoms after COVID-19 mRNA vaccination. Nonetheless, we cannot rule out whether mRNA vaccines were the sole cause of the cardiovascular

outcomes. Future studies are necessary to confirm the true relationship and strength of association between the COVID-19 mRNA vaccines and cardiovascular complications reported in this review. Further research is warranted on the extent to which a SARS-CoV-2 infection can itself elicit adverse downstream cardiovascular effects [18–23, 25–28]. While the race towards the development of novel, all-encompassing vaccinations runs astride the pharmaceutical giants, it is pivotal to factor in the ramifications that these vaccines can elicit. Nevertheless, the true challenge arises from a concoction of the paucity of data that exists, and the inability to identify the true etiologies of these cardiovascular outcomes in the aforementioned patient cohorts.

## 6. Conclusion

This review highlights various cardiovascular complications associated with COVID-19 mRNA vaccines in order to emphasize that early recognition of similar presentations can lead to prompt treatment and improved patient outcomes. While the severity of these cases cannot be understated, the present review reinforces that the benefits and effectiveness of the COVID-19 mRNA vaccines trump their risk of the aforementioned sequelae.
