**Polycystic kidney disease (PKD)** has become recognized as a genetically and clinically heterogeneous condition, with new disease genes being discovered upon atypical presentation. Atypical presentation contrasts with the classic clinical picture of autosomal dominant PKD (ADPKD), which is characterized by symmetric bilateral kidney enlargement, presence of liver cysts, and a PKD-family history, often over several consecutive generations. Sequencing aberrations in the genes PKD1/PKD2 account for the vast majority of typical ADPKD (>90%); however, variants in new disease genes are to be considered upon atypical imaging patterns (unilateral, asymmetric, segmental, lopsided, or bilateral cystic disease with unilateral or bilateral kidney atrophy) or absence of typical extrarenal manifestations (e.g., liver or pancreas cysts, intracranial aneurysms, cardiac valve disease, colonic diverticula). Mechanistically, the

following 2 groups can be distinguished among these new PKD disease genes: (i) genes encoding for components of the endoplasmic reticulum  $(ALG5)^1$  $(ALG5)^1$   $ALG6^2$  $ALG6^2$   $ALGS^3$  $ALGS^3$  $ALG9<sup>4</sup>$  $ALG9<sup>4</sup>$  $ALG9<sup>4</sup>$   $DNAJB11<sup>5</sup>$  $DNAJB11<sup>5</sup>$  $DNAJB11<sup>5</sup>$ ) and (ii) genes whose products are located and functionally associated with the primary cilium (IFT140,<sup>[6](#page-2-5)</sup> NEK8<sup>[7](#page-2-6)</sup>) [\(Figure 1](#page-1-0)a). Upon biallelic alteration, virtually all these genes were previously associated with an early-onset syndromic condition within the spectrum of congenital disorders of glycosylation (ALG5, ALG6, ALG8, ALG9) or nephronophthisis related ciliopathies (IFT140, NEK8).

Check for updates

Among atypical presentations, PKD due to monoallelic pathogenic variants in IFT140 appears to be the predominant entity, characterized by an attenuated, mild natural history, with little to no incidences of kidney failure in midlife.<sup>[6](#page-2-5)[,8](#page-2-7),[9](#page-2-8)</sup> In their current article, Fujimaru et al.<sup>[10](#page-2-9)</sup> report on the relatively high prevalence of pathogenic IFT140 variants specifically among PKD-patients without overt family history (4.5% vs. 1% in PKD-patients with a family history). The authors argue that 10% to 25% of the total PKD population negate

familial affection and that such absence of family history may increase the likelihood of causal genetic findings in the spectrum of non-PKD1/2-mediated disease, notably ADPKD-IFT140. In their cohort of 157 adults with PKD  $(\geq 5)$ cysts/kidney), they employed a targeted panel of 69 to 92 cystic kidney disease genes, including IFT140. As a result, they found monoallelic diagnostic IFT140 variants in 4.5% of the cohort, variants in PKD1/2 in 32.5%, and variants in other cystic kidney disease genes (e.g., HNF1B, PKHD1, OFD1, NPHP4) in 4.5%. Similar to the initial description of  $ADPKD-IFT140<sup>6</sup>$ the authors report on minor liver involvement, but atypical renal cyst size and locations (large, exophytic cysts) with lower total kidney volume and better renal function, compared to classical ADPKD-PKD1/2. Prevalence of arterial hypertension was similar to that of patients with pathogenic variants in PKD1/2 and 3 out of 7 patients with pathogenic IFT140 variants and adequate cerebral imaging actually showed an intracranial aneurysm.

Nevertheless, some knowledge gaps for ADPKD-IFT140 remain. From this and previous studies, there is still insufficient data available on the prevalence of extrarenal disease: notably, the open question of whether intracranial aneurysms or retinal phenotypes are part of the disease spectrum, because the latter is commonly observed in patients with biallelic pathogenic variants in IFT140 (MIM #266920 and MIM #[6](#page-2-5)17781). $^6$  Phenotypic variability may also be due to additional hypomorphic variants, including variants of unknown significance. Ultimately, monoallelic and biallelic disease are

Figure 1. Overview on new autosomal dominant PKD genes with *IFT140* being the most prominent example. (a) Among the 10% of patients with genetically unresolved PKD, diagnostic variants in 1 of the 8 new disease genes can be found. Mechanistically, their gene products either play a role in the ER-based N-glycosylation process of the polycystins (PC1/2) (purple) or are associated with primary cilia function and signaling (light green). (b) Although renal disease severity decreases among the new ADPKD genes (with the exception of NEK8 p.Arg45Trp), the likelihood of (pseudo) sporadic disease is increased in this group compared to typical ADPKD-PKD1/ 2. ADPKD, autosomal dominant polycystic kidney disease; COPII, coat protein complex II; ER, endoplasmic reticulum; PKD, polycystic kidney disease.

likely to represent 2 ends of a continuum.

Despite the growing list of cystic kidney disease genes, in the study of Fujimaru et al.,<sup>[10](#page-2-9)</sup> pathogenic variants in cystic kidney disease genes have only been found in 41.4% of the 157 patients without familial affection. Even though an additional 20.4% of patients carried a variant of unknown significance in a cystic kidney disease gene, this still leaves almost 40% of the cohort genetically unresolved, compared to approximately 10% in patients with a family history. This may in part be explained by methodological limitations (e.g., panel sequencing). The diagnostic yield may have been higher with more sophisticated sequencing techniques such as (long-range) whole genome sequencing. Furthermore, other genetic (e.g., germline or somatic mosaicism) or nongenetic causes of kidney cysts (e.g., acquired renal cystic disease) remain a possibility. Nevertheless, the low estimated glomerular filtration rate (median 42.9 ml/min) and the relatively high prevalence of liver

cysts  $(57.1\%)$  suggest that  $PKD1/2$ variants might have been missed in these patients.

After all, the work by Fujimaru et  $al^{10}$  $al^{10}$  $al^{10}$  highlights the important contribution of pathogenic IFT140 variants in ADPKD-like phenotypes, especially for patients with milder disease and no documented familial affection.

In genetics, sporadic disease typically suggests de novo status, somatic mosaicism, or recessive inheritance. However, in sporadic PKD with atypical adult-onset presentation, it is important to consider dominant inheritance with incomplete penetrance, due to a pathogenic variant in one of the newly discovered dominant PKD genes. With the exception of NEK8, where a distinct recurrent de novo missense allele (p.Arg45Trp) accounts for neonatal PKD, this group of new PKD genes is overall associated with relatively mild cystic kidney disease. Sporadic cases are likely to be more frequent because parental affection was simply missed due to being oligosymptomatic or asymptomatic [\(Figure 1b](#page-1-0)). This phenomenon

contrasts with true sporadic disease. Instead, the case of missed parental affection may therefore be referred to as "pseudosporadic".

Because family history is part of the clinical diagnostic criteria for imaging-based diagnosis of ADPKD (Pei-Ravine criteria), ADPKD-IFT140 and other nonclassical forms of PKD can only be confirmed through genetic testing. Consequently, genetic testing has become increasingly important for the differential diagnosis of PKD in adults, aids in the prediction of disease progression, and guides targeted treatment. For now, we do not have sufficient evidence to recommend cascade testing of relatives for nonclassical forms of PKD. However, informing patients about the overall favorable prognosis of ADPKD-IFT140 and other non PKD1/2-mediated disease is a key aspect of genetic counselling and may provide great relief for affected families.
