Endoscopic submucosal dissection

Preoperative biopsy

Case report

ABSTRACT

INTRODUCTION: Gastric adenocarcinomas with low grade atypia may be difficult to diagnose as gastric cancer by preoperative biopsy. We report an extremely well-differentiated adenocarcinoma (EWDA) of the stomach which appeared like a submucosal tumor diagnosed by preoperative endoscopic submucosal dissection.

PRESENTATION OF CASE: A 70-year-old male was referred with a 3-month history of a submucosal-appearing lesion in the gastric wall found on endoscopy. Biopsies of the lesion were performed and were inconclusive for neoplasia. Endoscopic ultrasonography showed a low echoic tumor growing into the fourth layer of the gastric wall. It was difficult to identify the tumor by repeat biopsy. Endoscopic submucosal dissection of the lesion was performed and revealed adenocarcinoma, and laparoscopic total gastrectomy was performed. Histopathologic evaluation showed that the tumor was stage IIA (T3N0M0). There is no recurrence 12 months after resection.

DISCUSSION: Gastric EWDA are rare lesions, accounting for 0.6% of all gastric cancers. It is difficult to diagnose gastric EWDA especially if it appears like a submucosal tumor. This lesion was finally diagnosed by endoscopic submucosal dissection.

CONCLUSION: Endoscopic submucosal dissection may facilitate establishing the preoperative diagnosis of a tumor thought to be a gastric EWDA based on its endoscopic appearance and pathological findings.

1. Introduction

Some gastric adenocarcinomas have low-grade nuclear and structure atypia. Gastric extremely well-differentiated adenocarcinoma (EWDA) is defined as a neoplastic lesion consisting of highly differentiated neoplastic epithelium which mimics normal gastric mucosa or intestinal metaplastic mucosa with mild nuclear atypia, but has the ability to invade the gastric wall [1–4]. It also can be classified into gastric and intestinal phenotypes [1–4]. It is located in the middle or upper third of the stomach and appears like a submucosal tumor [1]. It has been reported that they are difficult to diagnose as gastric cancer by preoperative biopsy [5].

A patient presented with a lesion that could not be characterized despite repeated preoperative biopsies including a boring biopsy. Gastric EWDA was suspected based on the endoscopic appearance

like a submucosal tumor in the proximal gastric body and the lesion was finally identified after endoscopic submucosal dissection. To the best of our knowledge this is the first report of a gastric EWDA which appeared like a submucosal tumor diagnosed by endoscopic submucosal dissection.

This work is reported in accordance with SCARE criteria [6].

2. Presentation of case

A 70-year-old male was referred with a 3-month history of a depressed lesion on the posterior wall of the proximal gastric body at a routine endoscopic examination. At the age of 67, he underwent *Helicobacter pylori* eradication therapy which was confirmed negative 3 months later. The first endoscopic examination revealed a lesion with depressions in the center on the surface, but protruding as a whole and appeared like a submucosal tumor, located on the posterior wall of the proximal gastric body (Fig. 1A). It had an irregular microsurface pattern and microvascular pattern using magnifying blue laser imaging (Fig. 1B). A biopsy showed gastric mucosa with intestinal type glands and minimal architectural

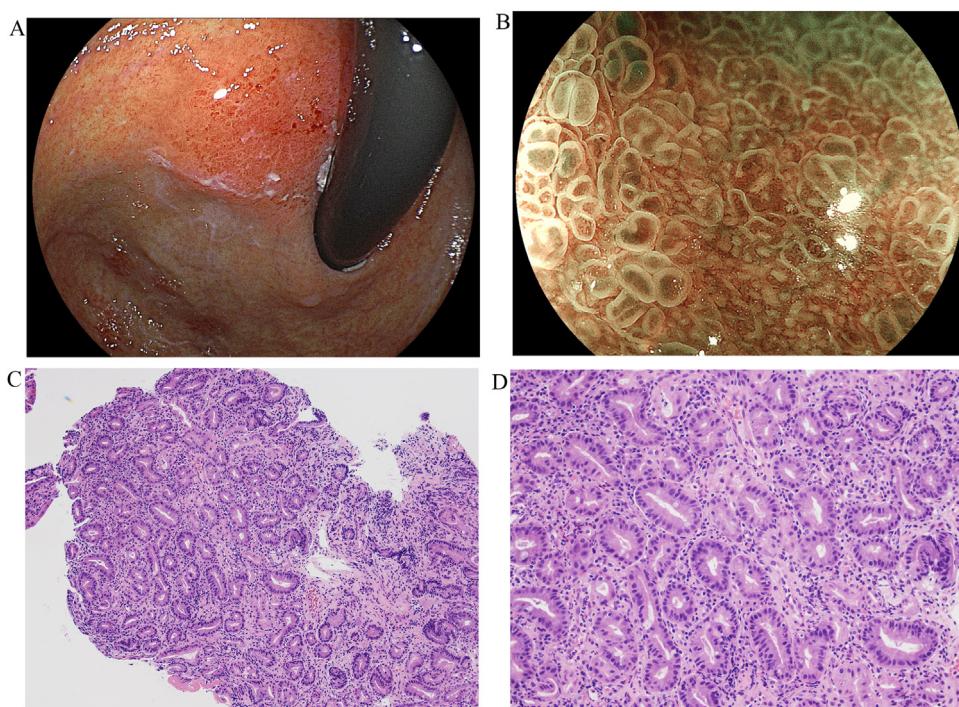

Fig. 1. A, B, C, D. Endoscopic examination showed a submucosal appearing lesion in the posterior wall of the proximal gastric body (1A). The lesion had an irregular microsurface pattern and microvascular pattern in the magnifying blue laser imaging (1B). Biopsy revealed atypical glands without architectural atypia and nuclear atypia (H&E, $\times 100$ (1C), $\times 200$ (1D)).

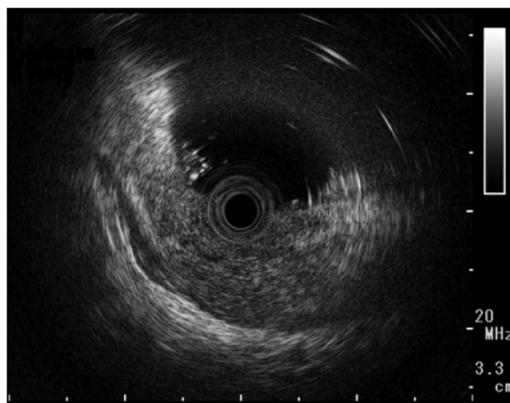

Fig. 2. Endoscopic ultrasonography showed a low echoic tumor extending into the fourth layer of the gastric wall.

abnormalities. The glands were comprised of eosinophilic columnar epithelium and a few scattered goblets cells with low-grade nuclear atypia (Fig. 1C, D). Immunohistochemical expression of p53 had a normal pattern. Although the diagnosis of EWDA was considered, reactive intestinal metaplasia was not excluded. Endoscopic ultrasonography showed a low echoic tumor growing into the fourth layer of the gastric wall (Fig. 2). Computed tomography scan did not show the tumor in the gastric wall and there was no evidence of metastases.

Although we considered that the tumor could be a gastric EWDA because of its endoscopic appearance, it was impossible to conclusively diagnose gastric cancer despite repeated preoperative biopsies including a boring biopsy. We thought that it was important to obtain a sufficient material including the deeper submucosal layer. Therefore, as a partial dissection to obtain an adequate sample of tissue from deeper in the lesion, an endoscopic submucosal dissection to establish a definitive diagnosis was performed (Fig. 3A). Histologically, intestinal-type glands were growing into

the submucosa, and the lesion diagnosed definitively as adenocarcinoma. Compared to the intramucosal component, infiltrating glands showed heterogeneous architecture with a thin epithelium and dilated lumen. The tumor had obvious involvement of both the lateral and vertical margins indicating incomplete dissection (Fig. 3B, C). The patient subsequently underwent laparoscopic total gastrectomy with lymph node dissection. Pathological examination of the resected stomach revealed that the tumor infiltrated the subserosa with moderate vascular invasion (Fig. 4A–C). Both proximal and distal margins were tumor free. No metastases were found in the lymph nodes. The tumor was finally classified as stage IIA (T3N0M0) according to the 2018 AJCC system. There is no evidence of recurrence 12 months after resection.

3. Discussion

Gastric EWDA are a rare type of gastric adenocarcinoma, which account for just 0.6% of all gastric cancers and for 0.1% of well-differentiated gastric cancers. It is reported that using a combination of at least three of six architectural features, including anastomosing glands, spiky glands, distended glands, discohesive cells, abortive glands, and glandular outgrowth is informative and useful for diagnosing intestinal-type EWDA.

The intestinal immunophenotype has a less aggressive biological behavior which is supported by a low Ki-67 and a lack of p53 or c-erbB2 protein overexpression [1,2].

A study showed that in 31 patients with gastric EWDA, 5 were diagnosed by, and 8 were suspected by, preoperative biopsy. In 7 patients, the lesions were similar to submucosal tumors [7]. Another study showed that in 9 patients reported with gastric EWDA, the tumors were located in the proximal or middle third of the stomach. They were polypoid masses appearing like Borrmann type 1 lesions or submucosal tumors mimicking Borrmann type 4. It is difficult to definitively diagnose gastric EWDA by preoperative biopsy, especially in patients with Borrmann type 4 lesions [5].

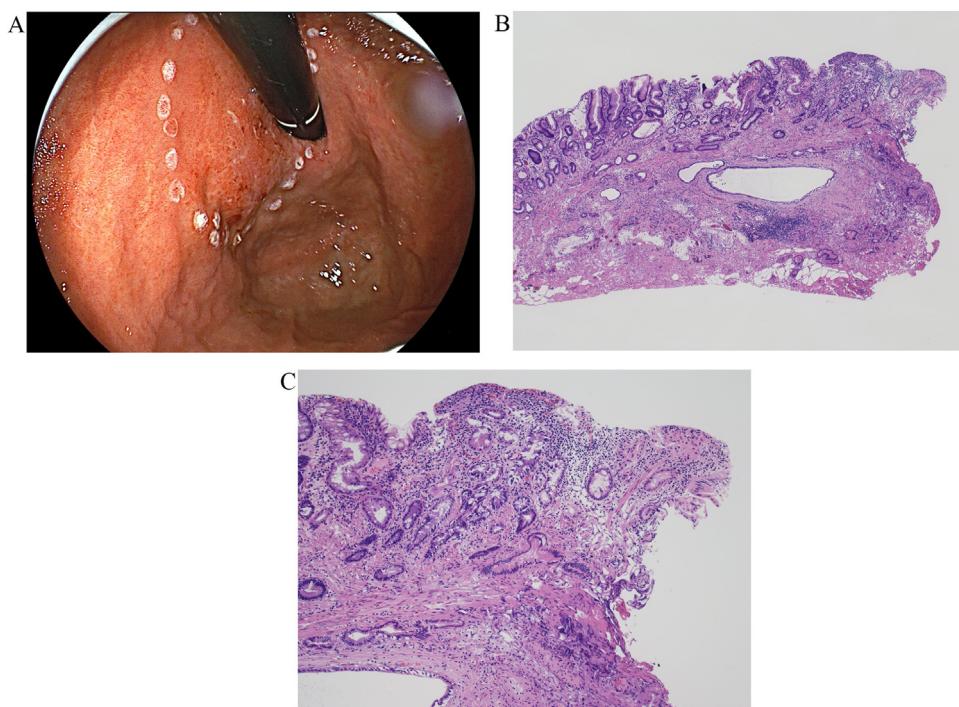

Fig. 3. A, B, C. Endoscopic submucosal dissection was performed (3A). The histopathologic examination of the specimen showed acidophilic columnar cancer cells indicating mild to moderate nuclear atypia infiltrated deeper than the submucosal layer with forming mucinous glands clearly. Both horizontal and vertical margins were positive (H&E, x40 (3B), x100 (3C)).

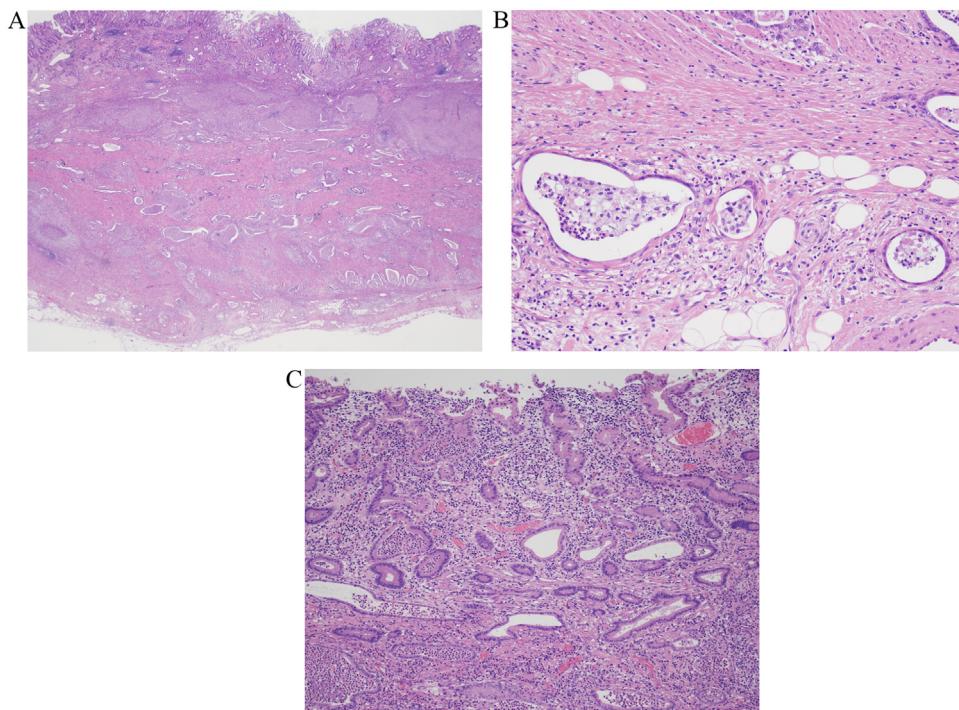

Fig. 4. A, B, C. Laparoscopic total gastrectomy was performed. The resected tumor had acidophilic columnar cancer cells indicating mild to moderate nuclear atypia infiltrating the mucosal layer to the subserosa with clear formation of mucinous glands (H&E, x12.5 (4A), x200 (4B), x100 (4C)).

In some patients, gastric cancer is advanced when the definitive diagnosis is established. In early gastric EWDA, the border between the normal mucosa and the cancer is difficult to distinguish. Therefore, the lateral margin tends to be positive if endoscopic submucosal dissection is performed for treatment and

the complete excision rate by endoscopic submucosal dissection is low [8,9].

To date, only 14 patients (including the present patient) with gastric EWDA with an elevated lesion appearing like a submucosal tumor have been reported. The pathological findings, operative procedure, and initial diagnostic procedures for these patients are

summarized in **Table 1**. Patients ranged from 42 to 77 years old and 12/14 were male. The diagnosis was established by preoperative biopsy in 0/14 patients. In most patients, resection was performed without a definitive preoperative diagnosis and diagnoses were made from the surgically excised specimen. Diagnoses were made by frozen section in 2/14 and after laparoscopic partial resection in 1/14. In the present patient, the diagnosis made after endoscopic submucosal dissection of the lesion. Gastric EWDA was suspected based on endoscopic findings. However, in all specimens obtained preoperatively, by endoscopic submucosal dissection and surgical resection, there were no architectural features in the gastric mucosa retrospectively and it was difficult to diagnose by preoperative biopsy. However, endoscopic submucosal dissection of the lesion showed findings of infiltration and the six architectural features in the submucosa, diagnosing gastric EWDA. It is important to assess the findings in the submucosa.

4. Conclusion

In patients with lesions without definitive pathological findings on biopsy, the diagnosis of a lesion suspected to be a gastric EWDA can be made based on endoscopic findings using endoscopic submucosal dissection to assess the findings in the submucosa. Due to their growth characteristics, formal resection may subsequently be needed.
