# Hemin-catalyzed oxidative oligomerization of *p*-aminodiphenylamine (PADPA) in the presence of aqueous sodium dodecylbenzenesulfonate (SDBS) micelles†

 Nemanja Cvjetan,<sup>a</sup> Reinhard Kissner,<sup>b</sup> Danica Bajuk-Bogdanović,<sup>c</sup> Gordana Čirić-Marjanović<sup>c</sup> and Peter Walde<sup>\*a</sup>

In a previous report on the enzymatic synthesis of the conductive emeraldine salt form of polyaniline (PANI-ES) in aqueous solution using PADPA (*p*-aminodiphenylamine) as monomer, horseradish peroxidase isoenzyme C (HRPC) was applied as a catalyst at pH = 4.3 with H<sub>2</sub>O<sub>2</sub> as a terminal oxidant. In that work, anionic vesicles were added to the reaction mixture for (i) guiding the reaction to obtain poly(PADPA) products that resemble PANI-ES, and for (ii) preventing product precipitation (known as the "template effect"). In the work now presented, instead of native HRPC, only its prosthetic group ferric heme *b* (= hemin) was utilized as a catalyst, and micelles formed from SDBS (sodium dodecylbenzenesulfonate) served as templates. For the elaborated optimal reaction conditions, complementary UV/vis/NIR, EPR, and Raman spectroscopy measurements clearly showed that the reaction mixture obtained after completion of the reaction contained PANI-ES-like products as dominating species, very similar to the products formed with HRPC as catalyst. HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonate) was found to have a positive effect on the reaction rate as compared to dihydrogenphosphate. This work is the first on the template-assisted formation of PANI-ES type products under mild, environmentally friendly conditions using hemin as a cost-effective catalyst.

## 1. Introduction

In a series of previous studies, it was shown that HRPC (horse-radish peroxidase isoenzyme C) can be successfully used in the presence of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) as a terminal oxidant in aqueous solution at pH = 4.3 and at room temperature for the synthesis of oligomeric and polymeric products rich in the conductive emeraldine salt form of linear polyaniline (PANI-ES) (Fig. 1). As monomers, either aniline,<sup>1–4</sup> the aniline dimer *p*-aminodiphenylamine (PADPA)<sup>5</sup> (Fig. 1), or mixtures of aniline and PADPA<sup>6</sup> were used. Moreover, for obtaining reaction products that contain substantial amounts of the ideal PANI-ES repeating unit, *i.e.*, half oxidized and protonated linear tetraaniline (Fig. 1), the presence of aggregates of anionic amphiphiles (mainly micelles or vesicles)<sup>1,7</sup> or anionic polyelectrolytes<sup>8</sup> as "templates" was shown to be essential. One of the roles these templates play in the

reaction mixture is to accumulate the monomers by electrostatic and hydrophobic interactions, thereby increasing their local concentration. As a consequence, once the monomers are oxidized by HRPC/H<sub>2</sub>O<sub>2</sub>, the follow-up reactions are influenced by the templates in a positive way, leading to a desired coupling of the oxidized monomers so that finally PANI-ES repeating units are obtained.<sup>4,6,9–12</sup> The use of anionic vesicles from AOT (the sodium salt of bis(2-ethylhexyl) sulfosuccinate) turned out to be particularly suitable for these HRPC-catalyzed reactions,<sup>1,5,13</sup> but the reactions also proceeded well with micelles formed from SDBS (sodium dodecylbenzenesulfonate) (Fig. 1) using aniline as monomer.<sup>14</sup> In the presence of SDBS micelles, however, HRPC is less stable than in the presence of AOT vesicles.<sup>14,15</sup>

The idea behind the work presented now was to try to synthesize PANI-ES products from PADPA as monomer in the presence of SDBS micelles by using instead of HRPC its prosthetic group, ferric heme *b*† (Fig. 1).

† Electronic supplementary information (ESI) available. See <https://doi.org/10.1039/d2ra02198f>

† Although it has been suggested to use capital letters for specifying isolated, free hemes, *e.g.* heme *B*, and lowercase letters for hemes bound or associated to proteins (*i.e.*, heme *b*), in this work we do not make this distinction and always use "heme *b*" for both cases.<sup>78</sup> The extent of amphiphilicity of heme *b* depends on the degree of dissociation of the two carboxylic acids. At the pH value of the aqueous solutions used in this work, it is likely that the two carboxylic acids are not ionized at all.

**Fig. 1** Chemical structures of PADPA (= *p*-aminodiphenylamine); PANI-ES, the emeraldine salt form of linear polyaniline in the bipolaron (1) and conductive polaron (2) states; SDBS (= sodium dodecylbenzenesulfonate), hard type;<sup>15</sup> heme *b* in its ferric state (= Fe(III)protoporphyrin IX = por Fe<sup>III</sup> = hemin) with undissociated carboxylic acid groups at pH = 4.3;<sup>27</sup> and HEPES (= 4-(2-hydroxyethyl)-1-piperazineethansulfonic acid) in the zwitterionic form, which dominates at pH = 4.3 (deprotonated sulfonic acid and protonated N-atom close to the sulfonate group).<sup>55</sup>

In ferric heme *b*, Fe<sup>3+</sup> is coordinated to the four nitrogen atoms of protoporphyrin IX (Fig. 1). Other designations and abbreviations for ferric heme *b* are iron(III) protoporphyrin IX, Fe(III)PPIX, or porFe<sup>III</sup> (“por” standing for “protoporphyrin IX”). Ferric heme *b* is also known as hemin.<sup>16</sup> The commercially available hemin form contains a chloride ion at the 5<sup>th</sup> coordination position (porFe<sup>III</sup>-Cl).

The SDBS micelles used should play two essential roles in the reaction. They should not only serve as templates for the reaction, but also as a host for heme *b* by providing a local environment that ensures that heme *b* is in a catalytically active state. It is well known that heme *b* can form aggregates in an aqueous medium depending on the experimental conditions:  $\pi$ - $\pi$  dimers,  $\mu$ -oxo dimers, or large stacks of  $\mu$ -oxo dimers.<sup>17–19</sup> However, since only monomeric heme *b* is catalytically active, like at the active site of heme peroxidases<sup>20,21</sup> and of other heme proteins,<sup>22–24</sup> binding of heme *b* to the micelles must prevent heme aggregation. Therefore, the challenges of the work were to investigate (i) whether suitable conditions can be found under which heme *b* in the presence of anionic SDBS micelles is in catalytically active (monomeric) state towards PADPA as substrate, and (ii) whether PANI-ES-like oligo- or poly(PADPA) products are formed under these conditions.

The use of micelles for hosting heme *b* was studied before, although investigations of the average localization of heme *b* in micelles are still rare.<sup>25–27</sup> Based on previous reports, it is evident that only in the presence of certain types of micelle-forming

surfactants monomeric heme *b* is obtained.<sup>17</sup> So far, sodium dodecylsulfate (SDS) was most commonly used.<sup>25–30</sup>

Other possibilities for obtaining monomeric heme *b* in aqueous medium are to work at very low concentration,<sup>18–20</sup> to use human serum albumin, to which heme *b* binds in monomeric state at one of the hydrophobic binding sites,<sup>31–33</sup> or to form complexes with guanine (G)-rich DNAs (so-called G-quadruplex-DNAs).<sup>34–38</sup> In the latter case, the activity of such complexes towards aniline was reported by Shen *et al.* (2014).<sup>39</sup> Compared to G-quadruplex-DNAs or human serum albumin, however, SDBS micelles are not only simpler and cheaper hosts for heme *b*, but they can also serve as templates for the reaction (see above).

When heme *b* is placed in a non-protein environment, as in this work with SDBS micelles, a logical question arises: does the heme/SDBS micelle system follow the same catalytic cycle as heme peroxidases do (but perhaps less efficiently)? Or, do alternative mechanisms play a role? Scheme S-1, ESI,<sup>†</sup> provides an overview of the peroxidase cycle of HRPC.<sup>1,20,40–48</sup> In brief, the two-electron oxidation by H<sub>2</sub>O<sub>2</sub> of porFe<sup>III</sup> in the resting state of HRPC is followed by two one-electron oxidations of a reducing substrate, which is PADPA in the present case. Depending on the reducing substrate, non-enzymatic follow-up reactions lead to the final product(s), *i.e.*, oligo- or/and poly(PADPA).<sup>1,5</sup>

Regardless of the mechanism by which PADPA is oxidized, the performance of the heme/SDBS micelle system for the oxidation of PADPA to PANI-ES-like products was evaluated using the following criteria: (i) presence of spectroscopic

features of the reaction products that are characteristic for the formation of PANI-ES; (ii) presence of high amounts of favorable PANI-ES products; (iii) high “quality” of the formed products in terms of amount of linear PANI-ES products *vs.* amount of unfavorable products containing branches or phenazine-type units; and (iv) no precipitation of the products formed. Therefore, the aqueous reaction mixtures were analyzed by three complementary methods, UV/vis/NIR, EPR, and *in situ* Raman spectroscopy measurements. Characteristic absorption bands for PANI-ES-like products are in the near-infrared (NIR) and visible (vis) regions of the spectrum, at  $\lambda_{\max} \approx 800\text{--}1100$  nm, assigned to the  $\pi \rightarrow$  polaron transition,<sup>49</sup> and at  $\lambda_{\max} \approx 420$  nm, assigned to the polaron  $\rightarrow \pi^*$  transition,<sup>49</sup> with low absorption at  $\lambda \approx 500\text{--}600$  nm, indicative for the absence of extensive branching and absence of phenazine-type units.<sup>5,8</sup> Due to the presence of unpaired electrons, conductive PANI-ES products in their polaron form (Fig. 1) have an EPR spectrum.<sup>50–52</sup> Raman bands originating from C–N<sup>+</sup> stretching vibrations of the polaron form of PANI-ES are at wavenumbers ( $\tilde{\nu}$ ) in the range of  $1320\text{--}1380$  cm<sup>−1</sup>.<sup>11,53</sup>

As a part of the work with the hemin/SDBS micelle system, we also explored the possible effect the type of salt used for the preparation of the aqueous pH = 4.3 solution might have on the rate of reaction and on the product distribution. Although all previous investigations with HRPC and PADPA were carried out with a sodium dihydrogenphosphate solution of pH = 4.3 (0.1 M), in the current work with heme *b*, a pH = 4.3 solution of 0.1 M HEPES was mainly used. The reason for this is the known positive effect HEPES molecules have on the activity of ferric heme *b*.<sup>54</sup>

## 2. Materials and methods

### 2.1. Commercial materials

HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid), 99%, for biochemistry,  $M_w = 238.30$  g mol<sup>−1</sup>, lot A0233527, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) for analysis, 35 wt% solution in water, stabilized, lot: A0352305 were from Acros Organics. Sodium phosphate monobasic (sodium dihydrogenphosphate, NaH<sub>2</sub>PO<sub>4</sub>), ReagentPlus,  $\geq 99.0\%$ , lot BCBQ6142V, was purchased from Sigma-Aldrich. PADPA (*p*-aminodiphenylamine, *N*-phenyl-*p*-phenylenediamine), 98%,  $M_w = 184.24$  g mol<sup>−1</sup>, lot MKBX9690V was from Aldrich Chemistry. PADPA was recrystallized from *n*-hexane as described before.<sup>52</sup> Hemin from porcine, BioXtra,  $\geq 97.0\%$  (HPLC), lot BCCB6735,  $M_w = 651.94$  g mol<sup>−1</sup>, was from Sigma. SDBS (dodecylbenzenesulfonic acid sodium salt, hard type),  $>95\%$  (T),  $M_w = 348.48$  g mol<sup>−1</sup>, was purchased from TCI Chemicals. Dimethyl sulfoxide (DMSO), Analytical reagent, lot 18K084026, was from VWR Chemicals, and *n*-hexane, for liquid chromatography, LiChrosolv, was from Merck. HRPC (horseradish peroxidase isoenzyme C), PEO-131, grade I, 271 U mg<sup>−1</sup>, RZ  $\geq 3$ , lot 8153665000 was from Toyobo Enzymes. TMB (3,3',5,5'-tetramethylbenzidine), lot BCBV1333

was purchased from Aldrich Chemistry. Polypropylene Eppendorf tubes (2 mL reaction tubes) were purchased from Greiner Bio-One GmbH.

### 2.2. Preparation of stock solutions

#### 2.2.1. Aqueous pH 4.3 HEPES or phosphate salt solution.

Two different salt solutions of pH = 4.3 were prepared in glass bottles, either by using HEPES salt or NaH<sub>2</sub>PO<sub>4</sub>. The salts were dissolved in Milli-Q water to yield in both cases 0.1 M. The pH was adjusted to pH = 4.3 by using 2 M HCl. Depending on the type of experiment, one of the two pH 4.3 salt solutions was used for preparing the reaction mixture and also for the preparation of micellar solutions of SDBS.

**2.2.2. SDBS stock solutions.** Stock solutions of SDBS (40.0 mM) were prepared by dissolving 55.8 mg of SDBS in 4 mL of one of the two aqueous pH 4.3 solutions. After preparation, the solutions were stored at room temperature (RT,  $T \approx 25$  °C) and used within 2 weeks.

**2.2.3. HRPC stock solutions.** Stock solutions of HRPC were prepared by dissolving  $\approx 4.0$  mg of HRPC in 1 mL of 0.1 M sodium phosphate buffer solution (pH = 7.0), yielding a HRPC concentration of  $\approx 70$   $\mu$ M. The exact concentration was determined spectrophotometrically by using as molar absorption  $\epsilon_{403} = 102\,000$  M<sup>−1</sup> cm<sup>−1</sup> which gave a concentration of 77.6  $\mu$ M.<sup>16</sup> Such stock solution was kept at  $T = 4$  °C. It remained very stable and could be used for at least for up to 2 years after preparation. For carrying out the reactions, stock solutions of lower HRPC concentration (0.8  $\mu$ M) were freshly prepared before use. This was done by adding 10  $\mu$ L of the 77.6  $\mu$ M HRPC stock solution to 990  $\mu$ L of the appropriate aqueous pH 4.3 solution.

**2.2.4. Hemin stock solution.** A hemin stock solution (6.0 mM) was prepared by dissolving 4.17 mg of hemin powder in 1069  $\mu$ L of DMSO. This solution was freshly prepared (used within a day), due to a previous report on the adsorption of hemin onto plasticware.<sup>56</sup>

**2.2.5. PADPA stock solution.** A stock solution of PADPA (150 mM) was prepared in Eppendorf tubes by dissolving 13.8 mg of recrystallized PADPA in 500  $\mu$ L of DMSO. This solution was freshly prepared before use.

**2.2.6. H<sub>2</sub>O<sub>2</sub> stock solution.** A hydrogen peroxide stock solution (200 mM) was freshly prepared in Eppendorf tubes before use by dissolving 19.3  $\mu$ L of 35 wt% hydrogen peroxide solution ( $\approx 10.4$  M) in 980.7  $\mu$ L of Milli-Q water.

### 2.3. Preparation and analysis of reaction mixtures

**2.3.1. Reaction mixture preparation.** Unless otherwise stated, all reactions were carried out in 2 mL Eppendorf tubes at RT. If not mentioned else, the reaction time was always 24 h, and the final volume of all reactions was 1 mL. In cases where hemin was used as catalyst, the order of addition of the different stock solutions was the following: (1) aqueous pH 4.3 solution containing either 0.1 M HEPES or 0.1 M phosphate salt, (2) SDBS stock solution, (3) hemin stock solution, (4) PADPA stock solution, and (5) H<sub>2</sub>O<sub>2</sub> stock solution. The initial concentrations in the reaction mixture were: 5.0 mM SDBS, 10  $\mu$ M hemin, 1.0 mM PADPA, and 1.0 mM H<sub>2</sub>O<sub>2</sub>. In order to avoid any effects

§ For the pH = 4.3 conditions used for the reaction, the “buffer” salts used, HEPES or dihydrogenphosphate, do not act as buffers since pH = 4.3 is too far away from the corresponding pK<sub>a</sub> values of the two salts.

of DMSO on the physical state of hemin,<sup>56</sup> the total DMSO content was kept below 1 vol%. When HRPC was used as catalyst, the order of addition of the stock solutions was the following: (1) aqueous pH 4.3 solution containing 0.1 M HEPES or 0.1 M phosphate salt, (2) SDBS stock solution, (3) PADPA stock solution, (4) HRPC stock solution, and (5) H<sub>2</sub>O<sub>2</sub> stock solution. The initial concentrations in the reaction mixture were: 3.0 mM SDBS, 30 nM HRPC, 1.0 mM PADPA, and 1.0 mM H<sub>2</sub>O<sub>2</sub>. In both systems, after the addition of each component, the reaction was gently mixed by flipping the Eppendorf tube with a closed cap up and down. When controls were performed, the order of addition of the stock solutions stayed the same, just one of the stock solutions was not used but replaced by an appropriate amount of the aqueous pH 4.3 solution.

**2.3.2. UV/vis/NIR, EPR and Raman spectroscopy measurements.** UV/vis/NIR: for all reactions which were carried out in 2 mL Eppendorf tubes and analyzed after a reaction time of 24 h, a volume of 350  $\mu$ L was withdrawn from the reaction mixture and poured into a quartz cuvette (0.1 cm path length), and the UV/vis/NIR absorption spectrum was recorded with a JASCO V-670 spectrophotometer. Time-dependent changes of the absorption spectrum during the course of the reaction were carried out by running the reaction inside the quartz cuvette (*in situ* measurements). For this, the reaction mixture was first prepared in an Eppendorf tube, followed by immediate removal of a volume of 350  $\mu$ L from the reaction mixture and placing it into a quartz cuvette (0.1 cm path length). The absorption spectrum was then recorded every 15 min (up to 24 h). EPR: three identical reaction mixtures were prepared in 2 mL

Fig. 2 UV/vis/NIR absorption spectra of reaction mixtures prepared in HEPES solution containing hemin as catalyst, PADPA as monomer, and SDBS micelles, either with added H<sub>2</sub>O<sub>2</sub> (1, solid line), or without added H<sub>2</sub>O<sub>2</sub> (2, dashed line), recorded after a reaction time  $t = 24$  h at RT. Reaction conditions: 0.1 M HEPES, pH = 4.3; [hemin] = 10  $\mu$ M; [PADPA]<sub>0</sub> = 1.0 mM; [SDBS] = 5.0 mM; [H<sub>2</sub>O<sub>2</sub>]<sub>0</sub> = 1.0 mM (for 1). The contribution of hemin to  $A_{400}$  ( $l = 0.1$  cm) is  $\approx 0.066$  or less; and to  $A_{500}$  and  $A_{610}$  ( $l = 0.1$  cm)  $\approx 0.012$  and  $\approx 0.005$ , respectively, see Fig. S-3.†

Fig. 3 UV/vis/NIR absorption spectra of reaction mixtures prepared in HEPES solution containing HRPC as catalyst, PADPA as monomer, and SDBS micelles, either with added H<sub>2</sub>O<sub>2</sub> (1, solid line), or without added H<sub>2</sub>O<sub>2</sub> (2, dashed line), recorded after a reaction time  $t = 24$  h at RT. Reaction conditions: 0.1 M HEPES, pH = 4.3; [HRPC] = 30 nM; [PADPA]<sub>0</sub> = 1.0 mM; [SDBS] = 3.0 mM; [H<sub>2</sub>O<sub>2</sub>]<sub>0</sub> = 1.0 mM (for 1).

Eppendorf tubes. The tubes were stored at RT. After a predetermined time, the entire reaction mixture of one of the three tubes was poured into a flat quartz cell, and the EPR spectrum was measured with a Bruker EMX X-band spectrometer. Raman: Raman spectra of the reaction mixtures were recorded with a DXR Raman microscope (Thermo Scientific). A HeNe gas laser with an excitation wavelength of 633 nm was used for all measurements. The laser power on the sample was kept at 4.0 mW. The reaction mixtures were prepared in 2 mL Eppendorf tubes and stored at RT. At predetermined times, 10  $\mu$ L aliquots of the reaction mixture were transferred into the sample wells of the sample platform (Gold EZ-Spot Micro Mount sample slide, Thermo Scientific). After filling the well with the sample of the reaction mixture, the slide with the sample was placed on an X-Y motorized sample stage, and the laser beam was focused on the sample at an objective magnification of 10 $\times$ . The scattered light was analyzed by the spectrograph with a 600 lines mm<sup>-1</sup> grating. The exposure time was 10 s, and 10 exposures per spectrum were taken. Automatic fluorescence correction was performed using the OMNIC software.

### 3. Results and discussion

#### 3.1. Determination of the “optimal reaction conditions” for poly(PADPA) formation with hemin as catalyst

With “optimal reaction conditions” we mean reaction conditions (i) at which the formed amount of favorable, dark-green, PANI-ES-like poly(PADPA) products is as high as possible, while (ii) the amount of unfavorable products containing branches and/or phenazine-type units is low. Moreover, (iii) the amount of products obtained from PADPA as monomer should allow UV/vis/NIR absorption measurements inside cuvettes with

a path length of 0.1 cm without dilution of the reaction mixture; and (iv) precipitation of intermediates and products during the reaction or after completion of the reaction should not occur. These requirements were set by ourselves for practical reasons since they allow a clear and simple screening of different reaction conditions by direct UV/vis/NIR measurements without the involvement of possible effects originating from post-reaction treatments and from reaction product isolation. Our main interest was in finding reaction conditions that resulted in the appearance of absorption bands at  $\lambda \approx 1000$  and 420 nm (as expected for PANI-ES-like products) and absence of strong bands at  $\lambda \approx 500\text{--}600$  nm (*i.e.*, absence of undesired branching and/or phenazine-type structure formation), see Introduction. Based on our previous work on the enzymatic oxidative oligomerization of PADPA,<sup>5</sup> the initial concentrations for the reactions with hemin were kept at  $[\text{PADPA}]_0 = 1.0$  mM and  $[\text{H}_2\text{O}_2]_0 = 1.0$  mM. Furthermore, based on previous literature reports on the catalytic activity of hemin, the concentration of hemin used in all measurements was kept constant at  $[\text{hemin}] = 10$   $\mu\text{M}$ .<sup>57–59</sup> This concentration is also useful for direct spectrophotometric measurements of hemin itself in the region of the Soret band ( $A_{400} (l = 1 \text{ cm}) \approx 0.5\text{--}1.2$ ), so that information about possible changes in the aggregation state of hemin upon changing the reaction medium (in the absence of PADPA, *i.e.*, without reaction) can be obtained.<sup>17</sup>

For reference reactions with HRPC, the PADPA and  $\text{H}_2\text{O}_2$  concentrations used were the same as in the case of the reactions with hemin,  $[\text{PADPA}]_0 = [\text{H}_2\text{O}_2]_0 = 1.0$  mM, and the HRPC concentration applied was the one applied in our previous work with AOT vesicles as templates:<sup>5</sup>  $[\text{HRPC}] = 30$  nM.

As mentioned in the Introduction, SDBS micelles were used for hosting hemin and as templates for the reaction. The determination of the optimal SDBS concentration was carried out separately for the hemin- and the HRPC-catalyzed reactions. For both optimizations, an aqueous 0.1 M HEPES solution with pH = 4.3 was used. The spectra measured after a reaction time of  $t = 24$  h in the presence of different SDBS concentrations are shown in Fig. S-1 and S-2, ESI.† The optimal SDBS concentration for the hemin system was found to be 5.0 mM, while for the HRPC system it is 3.0 mM. The same optimal SDBS concentrations were also obtained when an aqueous 0.1 M dihydrogenphosphate solution at pH = 4.3 was used instead of the HEPES solution (data not shown). For both systems, SDBS may play at least two roles, see Introduction. First, hemin (amphiphilic and positively charged at low pH if water molecules coordinate at the 5<sup>th</sup> and 6<sup>th</sup> coordination site) and HRPC (overall positively charged at pH = 4.3,  $pI(\text{HRPC}) = 8.8$ ,<sup>21</sup> are expected to bind to SDBS micelles. Therefore, the micelles localize the catalytic steps of the reaction. Second, cationic PADPA and (some of) the reaction intermediates and products are expected to bind to SDBS micelles, similarly to what was shown in the case of anionic AOT vesicles.<sup>11,52</sup> Such binding results in increased substrate concentration in the area of the micelles if compared to the concentration in bulk solution. At optimal reaction conditions, no matter whether hemin or HRPC was used, the reaction products remained dispersed in the aqueous solution for several days without visible precipitation.

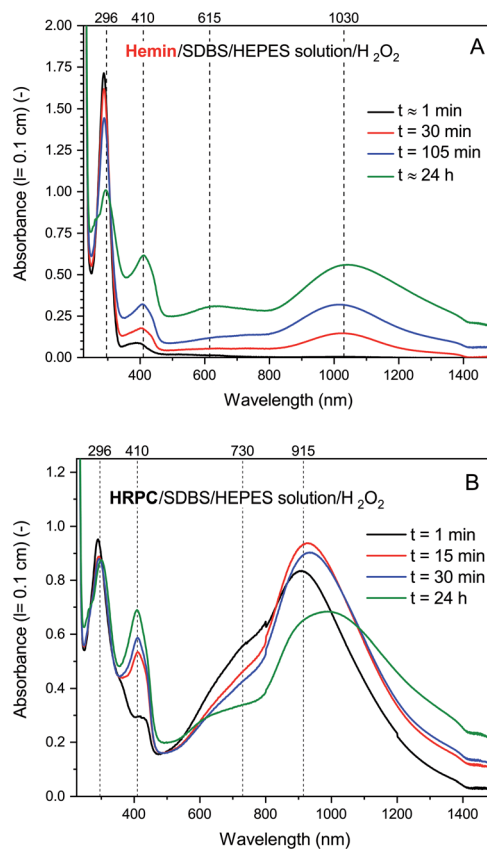

Fig. 4 UV/vis/NIR absorption measurements during the reaction of PADPA with either hemin (A) or HRPC (B) as catalyst and added  $\text{H}_2\text{O}_2$ . Reaction conditions: (A) 0.1 M HEPES pH 4.3 solution, [SDBS] = 5.0 mM,  $[\text{hemin}] = 10.0$   $\mu\text{M}$ ,  $[\text{PADPA}]_0 = 1.0$  mM,  $[\text{H}_2\text{O}_2]_0 = 1.0$  mM; (B) 0.1 M HEPES pH 4.3 solution, [HRP] = 30.0 nM, [SDBS] = 3.0 mM,  $[\text{PADPA}]_0 = 1.0$  mM  $[\text{H}_2\text{O}_2]_0 = 1.0$  mM. For the sake of clarity, only 4 measurements (the most prominent ones) per system are shown; a complete data set can be found in Fig. S-14 and S-15.† Total reaction time  $t \approx 24$  h, RT.

This supports the existence of product-SDBS micelle interactions, with SDBS acting as counterion (dopant) of the formed PANI-ES-like products with their positively charged backbone. Moreover, in the presence of SDBS micelles, hemin at 10  $\mu\text{M}$  is soluble in 0.1 M HEPES (or 0.1 M  $\text{H}_2\text{PO}_4^-$ ) at pH = 4.3, while without SDBS, at the same hemin concentration aggregates form (small particles that are visible by the naked eye), see Fig. S-3.†

### 3.2. Comparison of the reaction products obtained with hemin or HRPC as catalyst

**3.2.1. UV/vis/NIR spectroscopy measurements.** For the determined “optimal reaction conditions”, both with hemin or HRPC as catalyst, the reaction mixtures were analyzed and compared with each other by recording UV/vis/NIR absorption spectra after running the reaction for  $t = 24$  h at RT (see Fig. 2 and 3, solid lines). For both systems, the general features of the spectra are very similar. Absorption bands at  $\lambda_{\text{max}} \approx 1000$  and  $\approx 410$  nm are indications for the presence of favorable PANI-ES-

type products (see Introduction), although one has to be aware of the fact that in the case of hemin (10  $\mu\text{M}$ ), the Soret band absorption of the heme group contributes to  $A_{400}$  as well (see the legend of Fig. 2 and S-3†). The band at  $\lambda \approx 615$  nm most likely indicates the presence of undesired phenazine-like units.<sup>5</sup> The band at  $\lambda \approx 300$  nm originates in part from remaining PADPA. The intensity of this band is very high at the beginning of the reaction and decreases during the course of the reaction when PADPA is consumed (see below). Based on  $A_{300}$  (as well as  $A_{\approx 1000}$ ) measured after  $t = 24$  h, it seems that the PADPA conversion was a bit higher for the HRPC system as compared to the hemin system. The ratio of absorption intensities at  $\lambda \approx 1000$  and 610 nm was 1.8 for the hemin system ( $A_{1030}/A_{610}$ ) and 2.4 for the HRPC system ( $A_{980}/A_{610}$ ). This qualitative resemblance of the two UV/vis/NIR spectra of the reaction mixture after  $t = 24$  h is an indication that the products obtained from the two systems are similar but not identical. A higher value of  $\lambda_{\text{max}}$  for the  $\pi \rightarrow$  polaron transition band, 1030 nm for the hemin system compared to 980 nm for the HRPC system, indicates higher polaron delocalization and higher electrical conductivity of the poly(PADPA) products synthesized with hemin. The spectrum of the oligo- or poly(PADPA) products obtained with HRPC as catalyst were also compared with the spectrum of the products obtained from PADPA in our previous investigations, again with HRPC as catalyst and  $\text{H}_2\text{O}_2$  as terminal oxidant, but in the presence of AOT vesicles, again at pH = 4.3 in 0.1 M  $\text{H}_2\text{PO}_4^-$  solution, also with  $[\text{PADPA}]_0 = [\text{H}_2\text{O}_2]_0 = 1.0$  mM and  $[\text{HRPC}] = 30$  nM, see Fig. S-4.†<sup>5</sup> In both cases, there is a clear absorption band at  $\lambda_{\text{max}} = 410$  nm (with basically the same intensity), and there are strong absorptions in the NIR region of the spectrum,

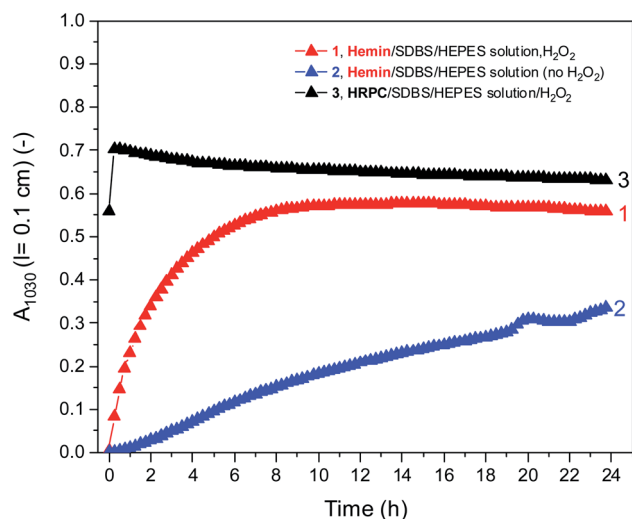

Fig. 5 Comparison of the changes of  $A_{1030}$  during the reaction of PADPA in 0.1 M HEPES solution (pH = 4.3) with either hemin or HRPC as catalyst at RT. Reaction conditions: (1) [hemin] = 10.0  $\mu\text{M}$ , [SDBS] = 5 mM, [PADPA]<sub>0</sub> = 1.0 mM, [ $\text{H}_2\text{O}_2$ ]<sub>0</sub> = 1.0 mM; (2) [hemin] = 10.0  $\mu\text{M}$ , [SDBS] = 5 mM, [PADPA]<sub>0</sub> = 1.0 mM, no  $\text{H}_2\text{O}_2$ ; (3) [HRPC] = 30 nM, [SDBS] = 3 mM, [PADPA]<sub>0</sub> = 1.0 mM, [ $\text{H}_2\text{O}_2$ ]<sub>0</sub> = 1.0 mM. Data points were obtained by running the reaction inside quartz cuvettes with a pathlength of  $l = 0.1$  cm and recording the spectrum every 15 min for up to  $t \approx 24$  h at RT.

with  $\lambda_{\text{max}} = 1097$  nm for the reaction run in the presence of AOT vesicles,<sup>5</sup> and  $\lambda_{\text{max}} = 980$  nm for the reaction in the presence of SDBS micelles (this work). In both cases, there is absorption in the region of  $\lambda = 500$ –600 nm with differences in absorption band positions (Fig. S-4†). Although we are not able to unambiguously explain the observed differences when using SDBS micelles vs. AOT vesicles as templates, a dependence of the absorption in the vis/NIR region of the absorption spectrum on the type of template used was also seen before in the case of the oxidative oligomerization of PADPA with *Trametes versicolor* laccase and  $\text{O}_2$  for reactions carried out at pH = 3.5.<sup>60</sup> Such differences most likely reflect not only differences in the molecular constitution (*i.e.*, the type of bonds formed between structural units), but also differences in (i) the degree of protonation of the nitrogen atoms present in the products, (ii) the oxidation state, (iii) the electron conjugation length, and/or (iv) molecular conformations.

Further comparative measurements were carried out for the hemin- and the HRPC-catalyzed reaction in the presence of 0.1 M dihydrogenphosphate instead of 0.1 M HEPES, again at pH = 4.3. The UV/vis/NIR absorption spectra of the reaction

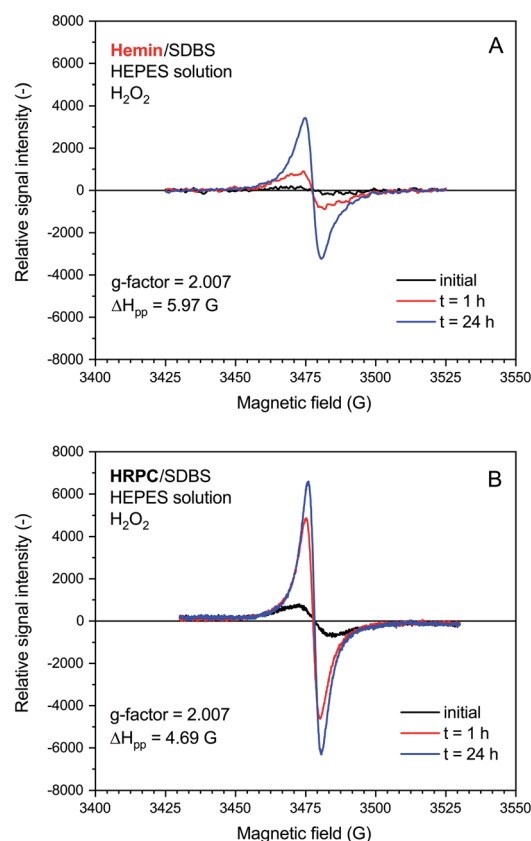

Fig. 6 EPR spectroscopy measurements for reaction mixtures prepared with 0.1 M HEPES, pH = 4.3, with either hemin (A) or HRPC (B) as catalyst. Reaction conditions: (A) [hemin] = 10.0  $\mu\text{M}$ , [SDBS] = 5.0 mM, [PADPA]<sub>0</sub> = 1.0 mM, [ $\text{H}_2\text{O}_2$ ]<sub>0</sub> = 1.0 mM; (B) [HRPC] = 30.0 nM, [SDBS] = 3 mM, [PADPA]<sub>0</sub> = 1.0 mM, [ $\text{H}_2\text{O}_2$ ]<sub>0</sub> = 1.0 mM. The reactions were run at RT inside Eppendorf reaction tubes and analyzed after  $t \approx 2$  min, 1 h or 24 h. G-factor and  $\Delta H_{\text{pp}}$  values are calculated for the spectrum recorded at  $t = 24$  h.

mixtures prepared with the  $\text{H}_2\text{PO}_4^-$  solution and incubated for  $t = 24$  h at RT are shown in Fig. S-5† together with the spectra obtained in the presence of the HEPES solution (data of Fig. 2 and 3). This comparison was made due to a previous report of Travascio and coworkers,<sup>54</sup> in which it was demonstrated that the catalytic activity of a DNA aptamer–hemin complex in the presence of Triton X-100 may depend significantly on the salt type used, and that the use of HEPES at pH = 8.0 may result in a more efficient reaction as compared to phosphate (analyzed with ABTS<sup>2-</sup>, 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonate), as substrate). Our aim was to find out whether a similar salt-type dependence of the activity of hemin also exists in the case of PADPA as substrate in the presence of SDBS micelles. The measurements showed that this is indeed clearly the case (Fig. S-5†). Although there was no big difference in the absorption peak positions for the two systems (at  $\lambda \approx 1030$ – $1080$ ,  $400$  nm, and  $615$  nm), two observations are obvious: (i)  $A_{\approx 1000}$  and  $A_{\approx 400}$  after  $t = 24$  h were much higher for the reaction mixture prepared with the HEPES solution, while  $A_{\approx 500-600}$  was in both cases about the same; (ii)  $A_{\approx 300}$  after  $t = 24$  h remained at a higher value for the reaction in the presence of dihydrogenphosphate as compared to the HEPES system (Fig. S-5†). These two observations clearly indicate higher conversion and a better “product quality” (higher  $A_{\approx 1000}/A_{500}$  and  $A_{\approx 1000}/A_{600}$  ratios) if the HEPES solution is used instead of the dihydrogenphosphate solution. For the reactions with HRPC, the band positions and intensities in the vis and NIR region of the absorption spectrum were very similar, although the spectrum recorded after  $t = 24$  h at RT for the reaction run in the HEPES solution had slightly higher intensities at  $\lambda \approx 400$  nm and at the band maximum in the NIR region. However, the band maximum position and intensity were different ( $\lambda_{\text{max}} = 980$  nm, with  $A_{980}$  (0.1 cm) = 0.68, for the HEPES solution and  $\lambda_{\text{max}} = 1074$  nm, with  $A_{1074}$  (0.1 cm) = 0.63, for the dihydrogenphosphate solution) (Fig. S-5†). These latter intensities are similar to the value determined previously with AOT vesicles as templates (0.1 M  $\text{NaH}_2\text{PO}_4$ )<sup>5</sup> instead of SDBS micelles with the same  $[\text{PADPA}]_0$ ,  $[\text{H}_2\text{O}_2]_0$ , and  $[\text{HRPC}]$  (Fig. S-4,†  $A_{1100}$  (0.1 cm)  $\approx 0.68$  after  $t = 24$  at RT).

As an important result from this HEPES vs. dihydrogenphosphate comparison is that under the conditions used the presence of HEPES has a positive effect on the outcome of the hemin-catalyzed formation of poly(PADPA). Whether this positive “HEPES effect” is a direct consequence of the influence the HEPES molecules have on the catalytic activity of hemin, or whether it is an effect which originates from HEPES-substrate interactions, was investigated by using TMB (3,3',5,5'-tetramethylbenzidine) as substrate ( $[\text{TMB}]_0 = [\text{H}_2\text{O}_2]_0 = 0.3$  mM, pH = 4.3, see Fig. S-6†). The initial rate of TMB oxidation was about 3.6 times faster in the presence of HEPES as compared to dihydrogenphosphate. This supports a direct effect of HEPES on the catalytic activity of hemin, possibly by coordinating to the iron atom at the 5<sup>th</sup> coordination site. For the results presented in the following, the reaction mixtures usually contained 0.1 M HEPES at pH = 4.3 (optimal conditions). Only for comparative measurements, a 0.1 M  $\text{H}_2\text{PO}_4^-$  solution at pH = 4.3 was used as well.

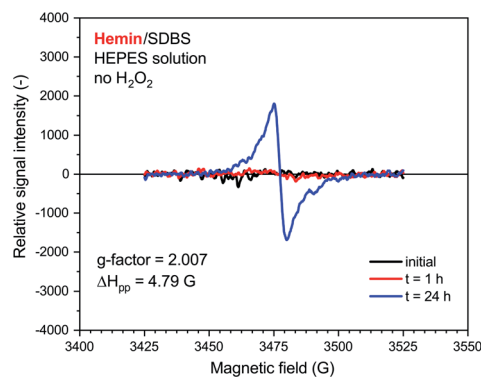

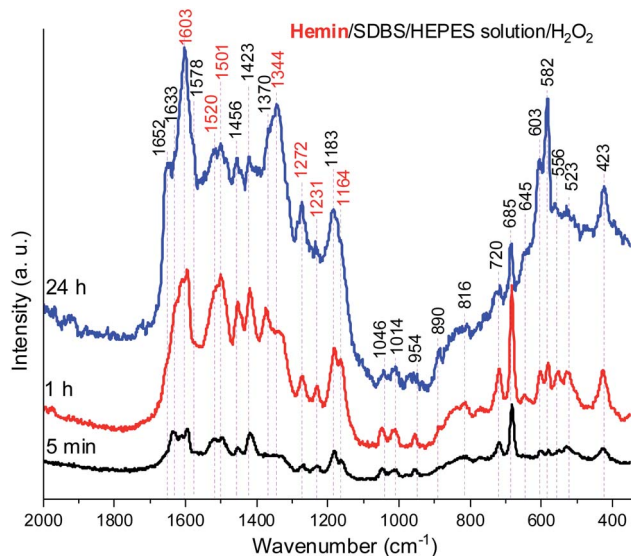

Fig. 7 EPR spectroscopy measurements for a reaction mixture prepared with 0.1 M HEPES, pH = 4.3, with hemin without added  $\text{H}_2\text{O}_2$ . Reaction conditions:  $[\text{hemin}] = 10.0$   $\mu\text{M}$ ,  $[\text{SDBS}] = 5.0$  mM,  $[\text{PADPA}]_0 = 1.0$  mM, no  $\text{H}_2\text{O}_2$ . The reaction was run at RT inside an Eppendorf reaction tube and analyzed after  $t \approx 2$  min (initial), 1 h or 24 h. G-factor and  $\Delta H_{\text{pp}}$  values are calculated for the spectrum recorded at  $t = 24$  h.

Different control measurements were carried out for both the hemin- and the HRPC-catalyzed reactions in the presence of 0.1 M HEPES and PADPA (1.0 mM) at pH 4.3, whereby one of the other components present in the optimal reaction mixtures was omitted, either SDBS, catalyst (hemin or HRPC), or hydrogen peroxide. In the case of the HRPC system, the reaction mixture did not turn green after  $t = 24$  h at RT if one of the mentioned components was absent (no absorption in the near-infrared region of the spectrum, *i.e.*, no formation of PANI-ES-like products), see Fig. S-7.† Without  $\text{H}_2\text{O}_2$  (but with HRPC and SDBS), no reaction occurred (the spectrum measured after  $t = 24$  h was the spectrum of PADPA (Fig. 3, dashed line); without HRPC (but with  $\text{H}_2\text{O}_2$  and SDBS), the absorption at  $\lambda \approx 300$  nm due to PADPA remained high after  $t = 24$  h (no significant PADPA conversion); without SDBS (but with HRPC and  $\text{H}_2\text{O}_2$ ), a reaction occurred but most of the brown products that formed precipitated, as already observed before.<sup>5</sup> Therefore, the oxidation and oligomerization or polymerization of PADPA into PANI-ES-like oligo- or poly(PADPA) products with HRPC requires the presence of  $\text{H}_2\text{O}_2$  as well as SDBS (Fig. S-7†). In the case of the hemin system, the situation is different. For two control measurements, the outcome was as expected: (i) in the absence of hemin (with  $\text{H}_2\text{O}_2$  and SDBS), or (ii) in the absence of SDBS (with hemin and  $\text{H}_2\text{O}_2$ ), no significant amounts of the green PANI-ES-like products were obtained (no significant absorption at  $\lambda \approx 1000$  nm, presence of a weak absorption centered around  $\lambda = 600$  nm) (Fig. S-8,† compare also with the spectrum shown in Fig. S-1,† for “no SDBS”). More interesting and somewhat surprising, however, was the outcome of the control measurements without  $\text{H}_2\text{O}_2$  (but with hemin and SDBS). The reaction proceeded quite well without added  $\text{H}_2\text{O}_2$ , resulting after  $t = 24$  h at RT in an absorption spectrum with  $\lambda_{\text{max}} = 1051$  nm with  $A_{1051}$  (0.1 cm) = 0.44 and  $\lambda_{\text{max}} = 412$  nm with  $A_{412}$  (0.1 cm) = 0.43, as compared to  $\lambda_{\text{max}} = 1030$  nm with  $A_{1030}$  (0.1 cm) = 0.60 and  $\lambda_{\text{max}} = 410$  nm with  $A_{410}$  (0.1 cm) = 0.64, for the reaction run under the “optimal conditions”, *i.e.*, in the presence of  $\text{H}_2\text{O}_2$ , hemin and SDBS (Fig. 2, dashed line and Fig. S-8†). This observed reactivity of hemin without  $\text{H}_2\text{O}_2$

**Fig. 8** Raman spectra of a reaction mixture prepared with an aqueous 0.1 M HEPES solution at pH 4.3, with [hemin] = 10.0  $\mu\text{M}$ , [SDBS] = 5 mM, [PADPA]<sub>0</sub> = 1.0 mM, [H<sub>2</sub>O<sub>2</sub>]<sub>0</sub> = 1.0 mM, recorded at  $t = 5$  min, 1 h, and 24 h at RT. The bands characteristic for PANI-ES products are labeled in red, see text; a.u., arbitrary units.

indicates not only (i) how insightful control measurements can be, but also (ii) that – under the conditions used (0.1 M HEPES, pH = 4.3) – the oxidation of PADPA with hemin in the absence of added H<sub>2</sub>O<sub>2</sub> cannot proceed *via* a peroxidase-like mechanism (see Scheme S-1<sup>†</sup>), where H<sub>2</sub>O<sub>2</sub> first oxidizes the heme group in a two-electron oxidation reaction to yield compound **I**, which then initiates the oxidation of the substrate (PADPA) in two consecutive one-electron oxidation reactions. Compound **I** formation – if compound **I** forms at all – must occur in a different way in the absence of H<sub>2</sub>O<sub>2</sub>. For the hemin-catalyzed reaction without added H<sub>2</sub>O<sub>2</sub>, the absorption at  $\lambda \approx 600$  nm after  $t = 24$  h at RT was lower than in the case of the reaction run under the “optimal conditions” (with H<sub>2</sub>O<sub>2</sub>) (Fig. 2). The ratio of  $A_{1051}/A_{600}$  for the reaction mixture where no H<sub>2</sub>O<sub>2</sub> was added was 3.0, as compared to  $A_{1030}/A_{600} = 1.9$  for the reaction run under “optimal conditions” (with H<sub>2</sub>O<sub>2</sub>). Understanding how the hemin-catalyzed oxidation of PADPA in the absence of H<sub>2</sub>O<sub>2</sub> occurs is an interesting challenge for detailed future investigations (see below).

For a direct comparison, Fig. S-9<sup>†</sup> shows the UV/vis/NIR absorption spectra of the reaction mixtures containing either hemin or HRPC and incubated for  $t = 24$  h at RT (in the HEPES solution with or without H<sub>2</sub>O<sub>2</sub>).

The same set of control measurements for the hemin- and HRPC-catalyzed reactions were also carried out in the presence of aqueous 0.1 M dihydrogenphosphate solution instead of 0.1 M HEPES at pH 4.3 (see Fig. S-10 and S-11<sup>†</sup>). Qualitatively, similar results were obtained when using the dihydrogenphosphate solution as compared to using the HEPES solution: For HRPC, there was no significant reaction without H<sub>2</sub>O<sub>2</sub> (Fig. S-11<sup>†</sup>); for hemin, a clear reaction also occurred without H<sub>2</sub>O<sub>2</sub>. Moreover, the absorption spectrum of the oligo-

or poly(PADPA) products obtained after  $t = 24$  h at RT was about the same for the reaction run in the H<sub>2</sub>PO<sub>4</sub><sup>-</sup> solution with H<sub>2</sub>O<sub>2</sub> as compared to without H<sub>2</sub>O<sub>2</sub> (Fig. S-10<sup>†</sup>). Obviously, the addition of H<sub>2</sub>O<sub>2</sub> had no beneficial effect at all if the reaction was run in the dihydrogenphosphate solution at pH = 4.3. This is different to what we observed with the HEPES solution, where the added H<sub>2</sub>O<sub>2</sub> still was advantageous (see Fig. S-5<sup>†</sup>): compared to the reactions run in the dihydrogenphosphate solution with hemin and PADPA, the reactions in HEPES solution were more efficient (clearly higher intensity in the NIR region of the absorption spectrum of the products obtained).

Using TMB as substrate and measuring the initial rate of TMB oxidation in the presence of hemin, qualitatively the same results were obtained as with PADPA, see Fig. S-12 and S-13:<sup>†</sup> (i) with the HEPES solution, TMB was also oxidized without added H<sub>2</sub>O<sub>2</sub>, but the TMB oxidation was much faster with added H<sub>2</sub>O<sub>2</sub> (Fig. S-12<sup>†</sup>); (ii) with the dihydrogenphosphate solution, the same initial rate of TMB oxidation was measured, independent on whether H<sub>2</sub>O<sub>2</sub> was added or not (Fig. S-13, ESI<sup>†</sup>); and (iii) with the HEPES solution, the initial rate of TMB oxidation in the presence of H<sub>2</sub>O<sub>2</sub> was  $\approx 3.6$  times faster than with the H<sub>2</sub>PO<sub>4</sub><sup>-</sup> solution (please compare Fig. S-12 and S-13<sup>†</sup>).

Overall, the “best” conditions for oxidizing PADPA to PANI-ES-like oligo- or poly(PADPA) products with hemin is to use the HEPES solution with added H<sub>2</sub>O<sub>2</sub> at the optimal reaction conditions already mentioned above: 0.1 M HEPES, pH = 4.3; [SDBS] = 5.0 mM; [hemin] = 10  $\mu\text{M}$ , [PADPA]<sub>0</sub> = 1.0 mM; [H<sub>2</sub>O<sub>2</sub>]<sub>0</sub> = 1.0 mM.

In Fig. 4, the time-dependent changes of the UV/vis/NIR absorption spectrum for the hemin- and the HRPC-catalyzed oxidative oligomerization of PADPA in the presence of SDBS micelles and with added H<sub>2</sub>O<sub>2</sub> in the HEPES solution are shown.

With hemin, the development of the UV/vis/NIR absorption spectrum over time is relatively simple. There is an increase of absorption above  $\lambda \approx 380$  nm over time with a clear appearance of bands centered around  $\lambda \approx 1030$  and  $\approx 410$  nm (indication of the formation of favorable PANI-ES-type products). A broad band in the region of  $\lambda \approx 615$  nm is also clearly developing, which indicates formation of unfavorable products containing phenazine-type units. There is also a decrease of absorbance at  $\lambda \approx 300$  nm, which is an indication of PADPA being consumed during the reaction. The rate of reaction but not the pattern of the spectral evolution was affected by the type of salt present (HEPES *vs.* dihydrogenphosphate) and the presence or absence of H<sub>2</sub>O<sub>2</sub> (see Fig. S-16–S-18<sup>†</sup>). The fastest initial rate of spectral development in the hemin-catalyzed system was observed when the HEPES salt and H<sub>2</sub>O<sub>2</sub> were used, *i.e.*, the “optimal reaction conditions”.

With HRPC, the development of the UV/vis/NIR absorption spectrum with time was rather different from the spectral development of the reaction mixtures containing hemin. During the first 30 min, there was a sharp increase in absorbance of the bands positioned at  $\lambda \approx 410$  and  $\approx 915$  nm, which indicates the presence of PANI-ES-type products. In addition, there was a decrease in absorbance at  $A_{296}$ , which shows that PADPA was consumed during the reaction. After 30 min, there was a slow decrease of  $A_{915}$  and at the same time an increase of

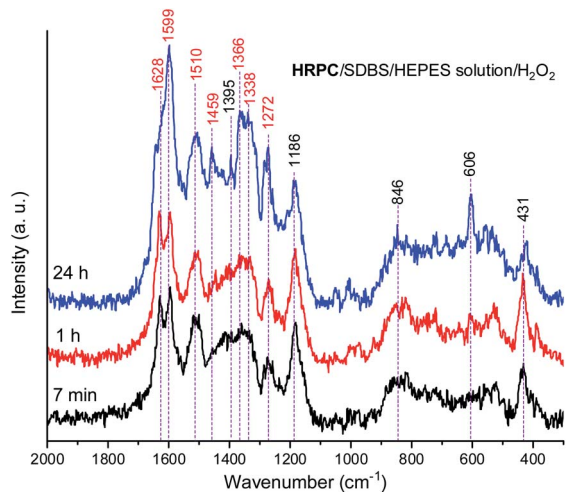

Fig. 9 Raman spectra of a reaction mixture prepared with an aqueous 0.1 M HEPES solution at pH 4.3, with [HRPC] = 30.0 nM, [SDBS] = 3.0 mM, [PADPA]<sub>0</sub> = 1.0 mM, [H<sub>2</sub>O<sub>2</sub>]<sub>0</sub> = 1.0 mM, recorded at *t* = 7 min, 1 h, and 24 h at RT. The bands characteristic for PANI-ES products are labeled in red, see text; a.u., arbitrary units.

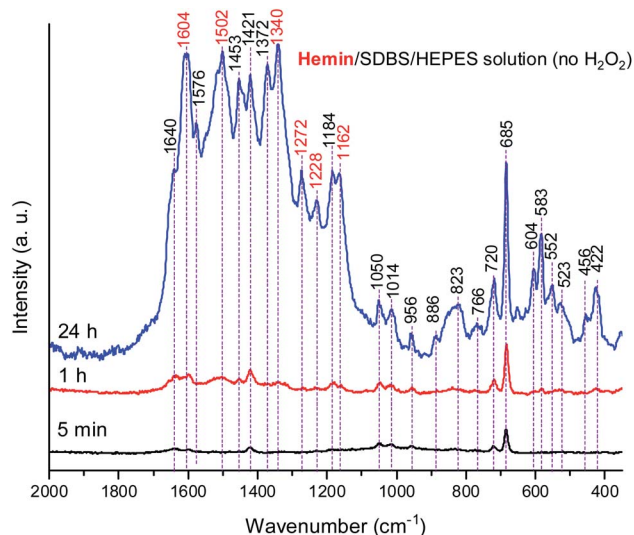

Fig. 10 Raman spectra of a reaction mixture prepared with an aqueous 0.1 M HEPES solution at pH 4.3, with [hemin] = 10.0 μM, [SDBS] = 5 mM, [PADPA]<sub>0</sub> = 1.0 mM, no H<sub>2</sub>O<sub>2</sub>, recorded at *t* = 5 min, 1 h, and 24 h at RT. The bands characteristic for PANI-ES products are labeled in red, see text; a.u., arbitrary units.

absorption intensity in the NIR region, at  $\lambda = 1200\text{--}1400$  nm, with an isosbestic point at  $\lambda \approx 1100$  nm. In addition, during the reaction, a shoulder at  $\lambda \approx 700$  nm was always present. Please note that the spectrum obtained after *t* = 24 h was slightly different from the one obtained for the same reaction conditions shown in Fig. 2. This difference originates from the different reaction containers used in the two cases (see Materials and methods).

Fig. 5 shows a direct comparison of the time-dependent changes of  $A_{1030}$  for the reaction mixtures prepared with the HEPES solution with hemin as catalyst, with (1) or without (2) H<sub>2</sub>O<sub>2</sub>. Data for the HRPC system with H<sub>2</sub>O<sub>2</sub> (3) are also shown (note that without H<sub>2</sub>O<sub>2</sub> no reaction occurred, see Fig. 3). In the case of the HRPC-catalyzed reaction,  $A_{1030}$  leveled off after *t*  $\approx$  15 min already, with a continuous slow decrease beyond this time due to a broadening of the spectrum into the NIR region (see Fig. 4B). For the hemin-catalyzed system, a plateau value was reached after *t*  $\approx$  8 hours in the presence of H<sub>2</sub>O<sub>2</sub>, while without added H<sub>2</sub>O<sub>2</sub>, the reaction clearly was much slower but  $A_{1030}$  kept gradually increasing (at least up to *t* = 24 h). This latter comparison is again a clear proof that for the hemin-catalyzed reaction the addition of H<sub>2</sub>O<sub>2</sub> is not necessary for the reaction to proceed (see Fig. 2), but that the rate of reaction with addition of H<sub>2</sub>O<sub>2</sub> is much faster than without added H<sub>2</sub>O<sub>2</sub>.

For the sake of completeness, kinetic measurements were also carried out by using the 0.1 M H<sub>2</sub>PO<sub>4</sub><sup>−</sup> solution instead of the 0.1 M HEPES solution, see Fig. S-19.† These measurements confirmed the lower activity of hemin in the H<sub>2</sub>PO<sub>4</sub><sup>−</sup> solution, in which the addition of H<sub>2</sub>O<sub>2</sub> had no beneficial effect at all (see also Fig. S-10†). For all further measurements by using EPR and Raman spectroscopy as analytical methods, the focus was on reaction mixtures prepared in 0.1 M HEPES at pH = 4.3. Nevertheless, the results obtained by using 0.1 M H<sub>2</sub>PO<sub>4</sub><sup>−</sup> at pH = 4.3

are also mentioned, with the corresponding data shown in the ESI.

**3.2.2. EPR spectroscopy measurements.** Under the elaborated optimal conditions for the hemin- and HRPC-catalyzed reactions (use of the HEPES solution), EPR measurements were carried out. In both cases, the presence of an EPR signal in the reaction mixtures that were prepared in Eppendorf reaction tubes and analyzed 1 h or 24 h after the start of the reactions was in agreement with the formation of the polaron form of PANI-ES type products (presence of unpaired electrons, with characteristic absorption at  $\lambda_{\text{max}} \approx 420$  and 800–1100 nm, see Introduction), see Fig. 6.

The rate of increase of the intensity of the EPR signal with time was slower if hemin was used as catalyst, as compared to HRPC. This is in agreement with the kinetic data obtained from the UV/vis/NIR absorption measurements, given that the presence of an absorption band in the NIR region of the spectrum is due to the presence of unpaired electrons that give rise to an EPR spectrum (see Introduction). The relative quantity of radicals produced till *t* = 24 h was significantly higher for the reaction run with HRPC as compared to hemin. The calculated *g*-factor values in both systems are identical (2.007, see Fig. 6) and are in good agreement with previously reported values for the emeraldine salt form of PANI.<sup>61,62</sup> The EPR signal width ( $\Delta H_{\text{pp}}$ ) for the spectrum recorded after *t* = 24 h indicates that the radical species are more uniform in the HRPC-catalyzed reaction ( $\Delta H_{\text{pp}} = 4.69$  G) than for the reaction run with hemin ( $\Delta H_{\text{pp}} = 5.97$  G), see Fig. 6.

A very weak EPR signal was also observed in the reaction mixture containing hemin without added H<sub>2</sub>O<sub>2</sub>, see Fig. 7. The relative intensity after *t* = 24 h was, however, much lower than for the reaction run with H<sub>2</sub>O<sub>2</sub> (compare Fig. 7 with Fig. 6). This is again in qualitative agreement with the UV/vis/NIR

absorption measurements, see Fig. 2. The  $g$ -factor determined for the spectrum recorded after  $t = 24$  h is identical with the ones described in Fig. 6. Interestingly,  $\Delta H_{pp}$  is more similar to the one determined for the spectrum of the HRPC system than for the spectrum of the hemin system with added  $H_2O_2$ .

EPR measurements were also carried out for reaction mixtures containing hemin in 0.1 M  $H_2PO_4^-$  solution (pH = 4.3) instead of 0.1 M HEPES (pH = 4.3), both in the presence and absence of  $H_2O_2$ , see Fig. S-20.† The data are again in good qualitative agreement with the UV/vis/NIR measurements, *i.e.* there was no beneficial effect of  $H_2O_2$  on the EPR signal intensity for the reaction with hemin in the reaction mixture containing dihydrogenphosphate. Furthermore, when the reaction mixture was carried out in the 0.1 M dihydrogenphosphate solution (pH = 4.3) the relative intensity of the EPR signal obtained when HRPC was used as catalyst was much higher than when hemin was used.

**3.2.3. Raman spectroscopy measurements.** For each of the aforementioned reaction mixtures using hemin or HRPC as catalyst under optimal reaction conditions, Raman spectroscopy measurements were carried out, again *in situ*, like in the case of the UV/vis/NIR and EPR measurements, *i.e.*, without isolation of the reaction products.

In Fig. 8, Raman spectra obtained for the reaction mixture containing hemin are shown for reaction times  $t = 5$  min, 1 h, and 24 h. For the reaction mixture analyzed after  $t = 5$  min, the Raman spectrum contained numerous bands that originate from starting materials and early reaction intermediates. As time progressed, the spectrum changed, and several bands that are typical for PANI-ES-like oligomeric products of PADPA appeared, as discussed in the following.

A number of bands that are characteristic for structural units of ordinary (“standard”) PANI can be observed at  $\tilde{\nu} = 1620$   $cm^{-1}$  (m, C–C stretching vibrations of benzenoid (B) rings,  $\nu(C-C)_B$ ), 1603  $cm^{-1}$  (m, C=C and C–C stretching vibrations of quinonoid (Q) and semiquinonoid (SQ) rings,  $\nu(C=C)_Q$  and  $\nu(C-C)_{SQ}$ ), 1520  $cm^{-1}$  (m, N–H bending vibration,  $\delta(N-H)$ ), commonly related to SQ (polaron) structures in PANI), 1501  $cm^{-1}$  (m, C=N stretching in quinonediimine units,  $\nu(C=N)_Q$ ), 1340  $cm^{-1}$  (w, C–N<sup>+</sup> stretching vibration in SQ (polaron) units,  $\nu(C-N^+)_{SQ}$ , characteristic for the conducting form of PANI, the emeraldine salt PANI-ES), 1272  $cm^{-1}$  (w, C–N stretching vibrations in B rings,  $\nu(C-N)_B$ ), 1231  $cm^{-1}$  (w,  $\nu(C-N)_B$ ), 1181  $cm^{-1}$  (m, C–H bending in-plane vibration of B ring,  $\delta(C-H)_B$ ), and 1164  $cm^{-1}$  (m, C–H bending in-plane vibration of Q ring,  $\delta(C-H)_Q$ ).<sup>53</sup> The Raman spectrum also indicates formation of structural units different from those of “standard” PANI, by the bands observed at  $\tilde{\nu} = 1633$   $cm^{-1}$  (m, attributable to C–C ring-stretching vibrations in phenazine-, *N*-phenylphenazine- and/or phenoxazine-type units, mixed with the C–C stretching vibration of the B ring,  $\nu(C-C)_B$ ), 1578  $cm^{-1}$  (sh, phenazine-type of units), 1456  $cm^{-1}$  (w, assignable to C–C ring stretching/C=N stretching in quinonoid type of units that are probably present in short chains/branches and in substituted phenazine- and *N*-phenylphenazine-type segments), 1423  $cm^{-1}$  (m, assignable to the ring-stretching vibration in phenazine-, *N*-phenylphenazine- and phenoxazine-type units, combined with a contribution

from DMSO), 1370  $cm^{-1}$  (vw,  $\nu(C-N^+)$  ring stretching vibration in substituted *N*-phenylphenazine-type units and to phenoxazine-type units/ $\tilde{\nu}(C-N^+)_{SQ}$  vibration in polaron-SQ structures of low delocalization), and 582  $cm^{-1}$  w, a band at similar position in spectra of PANI has been attributed to substituted phenoxazine-like units.<sup>53,63,64</sup> Such phenoxazine-like units could have been formed by the oxidative intramolecular cyclization of substituted *ortho*-aminophenol units, formed as products of hydrolysis of fully oxidized pernigraniline-like oligomers,<sup>65</sup> and substituted phenazine- and *N*-phenylphenazine-type units.<sup>53</sup> Contributions of C–S stretching vibration  $\nu(C-S)$  and  $SO_2$  deformation vibration  $\delta(SO_2)$  probably originating from the anion of SDBS (DBS) to the band at 582  $cm^{-1}$  are also possible.<sup>66</sup> The weak band in the spectrum at  $t = 5$  min observed at 603  $cm^{-1}$  could be assigned to  $\delta(SO_2)$  vibrations, originating from SDBS,<sup>66</sup> and benzenoid (B) ring deformation in PANI-like segments of oligo- or poly(PADPA).<sup>¶53,67</sup> In the Raman spectrum recorded at  $t = 1$  h, one can observe that the band at  $\tilde{\nu} = 1370$   $cm^{-1}$ , attributed to  $\nu(C-N^+)_{SQ}$  of polarons with lower delocalization/*N*-phenylphenazine and phenoxazine units, is well developed, being even stronger than the band at  $\tilde{\nu} = 1340$   $cm^{-1}$  assigned to  $\nu(C-N^+)_{SQ}$  of more delocalized polarons. However, in the Raman spectrum for  $t = 24$  h, the intensity ratio of these two bands is reversed, and the band at  $\tilde{\nu} = 1370$   $cm^{-1}$  becomes a shoulder of the band at  $\tilde{\nu} = 1344$   $cm^{-1}$ .

The relative intensities of the two bands characteristic of conducting PANI-ES at  $\tilde{\nu} = 1603$   $cm^{-1}$  and 1344  $cm^{-1}$  increased as the reaction time increased, so that they are present as the most intense bands in the Raman spectrum recorded at  $t = 24$  h, along with the band at 582  $cm^{-1}$ . The strong band at 1344  $cm^{-1}$  indicates a conductive nature of the poly(PADPA) product. Strengthening of the band at 1344  $cm^{-1}$  indicates an increase in the relative amount of delocalized polaron structures and consequently an increase in electrical conductivity of the oligo- or poly(PADPA) products over time. On the other hand, the relative intensity of the bands atypical for standard PANI, at 1633  $cm^{-1}$  and 1420  $cm^{-1}$ , decreased with reaction time in relation to the intensity of the mentioned PANI-ES bands. Additional interesting changes occur in the spectrum at  $t = 24$  h related to the spectrum at  $t = 1$  h: the bands attributed to “atypical segments” at  $\tilde{\nu} \approx 1456$   $cm^{-1}$  and 1420  $cm^{-1}$  become at  $t = 24$  h noticeably weaker compared to the bands of standard PANI-ES (*e.g.*, at  $\tilde{\nu} = 1603$   $cm^{-1}$  and 1344  $cm^{-1}$ ), the band at  $\tilde{\nu} = 1633$   $cm^{-1}$  disappears, and we observe a new band at  $\tilde{\nu} = 1652$   $cm^{-1}$  (which is also noticeably weaker compared to the bands of ordinary PANI at  $\tilde{\nu} = 1603$   $cm^{-1}$  and 1344  $cm^{-1}$ ) and a shoulder at  $\tilde{\nu} = 1578$   $cm^{-1}$ . The band at  $\tilde{\nu} = 1652$   $cm^{-1}$  could be attributed to the stretching of quinonoid C=O groups/C–C ring-stretching vibrations in phenoxazine-type units<sup>64</sup> with possible contributions of phenazine- and *N*-phenylphenazine-type units; C=O groups can be formed by the partial hydrolysis of iminoquinonoid C=N bonds.<sup>65</sup> The shoulder at  $\tilde{\nu} = 1578$   $cm^{-1}$  can also be attributed to substituted phenoxazine- and phenazine-type units.<sup>53</sup> The

¶ Sulfonates often have two bands in the range  $\tilde{\nu} = 610$ –500  $cm^{-1}$  due to  $SO_2$  deformation vibrations.<sup>66</sup>

bands at  $\tilde{\nu} = 1652$ ,  $1578$ , and  $585 \text{ cm}^{-1}$  indicate certain over-oxidation of oligo- or poly(PADPA) produced at long reaction times ( $t = 24 \text{ h}$ ). The relative intensities of the bands attributed to DMSO (at  $\tilde{\nu} = 1046$ ,  $720$ , and  $685 \text{ cm}^{-1}$ ) gradually decrease with reaction time, e.g., the band at  $\tilde{\nu} = 685 \text{ cm}^{-1}$  is very strong and the most intense band in the spectrum at  $t = 5 \text{ min}$ , while it is weak at  $t = 24 \text{ h}$ . This occurs due to the increase of the amount of oligo- or poly(PADPA) chains (as the reaction proceeds) on the surface of the reaction mixture “drop” which consequently leads to a reduction of surface concentration of DMSO. Thereby, as the reaction proceeds, oligo- or poly(PADPA) chains are becoming dominating species for Raman scattering instead of DMSO. We have observed an increase in the relative intensity of the band at  $\tilde{\nu} = 603 \text{ cm}^{-1}$  (assigned to  $\delta(\text{SO}_2)/\text{B}$  ring deformation in PANI-like segments) with an increase in reaction time (it is weak at  $t = 5 \text{ min}$ , medium at  $t = 1 \text{ h}$ , and strong at  $t = 24 \text{ h}$ ). This feature could be explained by an increase in oligo- or poly(PADPA) yield, and therefore, an increase in the surface concentration of DBS anions, which could serve as counterions (dopant ions), compensating positive charges of the poly(-PADPA) backbone. The prominent increase in the relative intensity of the band at  $\tilde{\nu} = 582 \text{ cm}^{-1}$  with increasing reaction time is observed. At  $t = 24 \text{ h}$ , it becomes very strong, bearing an intensity comparable to that of the band at  $\tilde{\nu} = 1344 \text{ cm}^{-1}$ . Such band development might come from an increase in the amount of phenoxazine-type units at longer reaction time due to the side processes connected with *ortho*-coupling of PADPA molecules. An additional factor could be an increase in DBS anions surface concentration. It should be noted that bands at similar positions,  $\tilde{\nu} = 576 \text{ cm}^{-1}$  (strong) and  $\tilde{\nu} \approx 607 \text{ cm}^{-1}$  (weak), are present in the solid-state Raman spectrum of PANI doped with dodecyl benzenesulfonic acid (PANI-DBSA).<sup>68</sup>

The Raman spectra of the reaction mixture containing HRPC as a catalyst for the reaction times  $t = 7 \text{ min}$ ,  $1 \text{ h}$  and  $24 \text{ h}$  (Fig. 9) qualitatively resemble the Raman spectra obtained with hemin as a catalyst. Nevertheless, there are certain differences which will be specified and discussed in the following.

In both systems, the one containing hemin and the other containing HRPC after a reaction time  $t = 24 \text{ h}$ , the bands attributed to standard PANI-ES ( $\tilde{\nu} \approx 1600 \text{ cm}^{-1}$  and  $\approx 1340 \text{ cm}^{-1}$ ) are stronger compared to the bands of atypical units ( $\tilde{\nu} \approx 1420\text{--}1440 \text{ cm}^{-1}$ ) and both spectra contain a band at  $\tilde{\nu} = 606 \text{ cm}^{-1}$ . It is interesting to note that the Raman spectra obtained in the reaction mixture containing HRPC as catalyst do not contain a band at  $\tilde{\nu} \approx 580 \text{ cm}^{-1}$  (attributable to phenoxazine-type units), and they do not show a strong “phenazine band” at  $\tilde{\nu} \approx 1420 \text{ cm}^{-1}$  in the initial phase of the reaction ( $t = 7 \text{ min}$ ), as it is the case for the reaction mixture with hemin as a catalyst. In addition, the spectra of the system with HRPC do not show a band at  $\tilde{\nu} \approx 680 \text{ cm}^{-1}$ , as was the case when hemin was used (Fig. 8). This indicates that the consumption of PADPA and the formation of poly(PADPA) oligo- or polymeric chains at the surface of the reaction mixture “drop” analyzed was faster in the system with HRPC than in the one containing hemin as a catalyst, which was also expected. This is in good agreement with the results from the UV/vis/NIR and EPR measurements (see above). When comparing the

Raman spectra recorded at  $t = 24 \text{ h}$  of the reaction mixtures with either HRPC or hemin as a catalyst, one more difference is evident. The spectrum for the system with HRPC contains a broad band in the region of the  $\nu(\text{C-N}^+)$  vibrations, with two peaks of similar intensity at around  $\tilde{\nu} = 1340 \text{ cm}^{-1}$  ( $\nu(\text{C-N}^+)_{\text{SQ}}$  vibration of more delocalized polaron structures) and  $\tilde{\nu} = 1366 \text{ cm}^{-1}$  ( $\nu(\text{C-N}^+)$  ring stretching vibration in substituted *N*-phenylphenazine- and phenoxazine-type units and  $\nu(\text{C-N}^+)_{\text{SQ}}$  vibration in polaron structures of low delocalization) (Fig. 9), while the spectrum of the system containing hemin (Fig. 8) has a strong  $\nu(\text{C-N}^+)_{\text{SQ}}$  band, at  $\tilde{\nu} = 1340 \text{ cm}^{-1}$  and a shoulder at  $\approx 1370 \text{ cm}^{-1}$ .

Due to the results obtained for the hemin-catalyzed reaction analyzed by UV/vis/NIR and EPR measurements (see above), Raman spectra of the reaction mixture containing hemin without added  $\text{H}_2\text{O}_2$  were also recorded, at  $t = 5 \text{ min}$ ,  $1 \text{ h}$ , and  $24 \text{ h}$ , see Fig. 10.

A comparison of the Raman spectra of the reaction mixtures without  $\text{H}_2\text{O}_2$  (Fig. 10) and with  $\text{H}_2\text{O}_2$  (Fig. 8) – both recorded after  $t = 24 \text{ h}$  – shows that the absorption band pattern in both cases is very similar. However, differences in the band intensities are obvious when spectra recorded after the same reaction time are compared. This is directly related to the lower PADPA monomer consumption for the reaction without  $\text{H}_2\text{O}_2$  (lower band intensities) as compared to the one with  $\text{H}_2\text{O}_2$  (higher band intensities).

Comparing the Raman spectra recorded at  $t = 24 \text{ h}$  for the two hemin systems (with and without  $\text{H}_2\text{O}_2$ ) in terms of ratios of intensities of the polaron  $\nu(\text{C-N}^+)_{\text{SQ}}$  band at  $\tilde{\nu} \approx 1340 \text{ cm}^{-1}$ , which is characteristic of standard conductive PANI-ES, and the bands at  $\tilde{\nu} \approx 1453$  and  $1420 \text{ cm}^{-1}$ , attributed to segments atypical for standard PANI-ES,  $I_{1340}/I_{1453}$ , and  $I_{1340}/I_{1420}$ , respectively, it is clear that these ratios are higher for the hemin system containing  $\text{H}_2\text{O}_2$  than the one without  $\text{H}_2\text{O}_2$ . Also, at  $t = 24 \text{ h}$ , the bands at  $\tilde{\nu} = 1372 \text{ cm}^{-1}$  and  $1576 \text{ cm}^{-1}$  are present as distinct bands in the spectrum of the hemin reaction mixture without  $\text{H}_2\text{O}_2$ , while in the spectrum of the hemin reaction mixture with  $\text{H}_2\text{O}_2$  they appear as shoulders, only. The bands at  $\tilde{\nu} = 604$  and  $583 \text{ cm}^{-1}$  have lower relative intensities in the spectrum of the hemin system without  $\text{H}_2\text{O}_2$  compared to these bands in the spectrum of the hemin system with  $\text{H}_2\text{O}_2$ .

Although it was not the main focus of the work, Raman spectroscopy measurements were also carried out for reaction mixtures prepared with  $0.1 \text{ M}$  dihydrogenphosphate solution instead of  $0.1 \text{ M}$  HEPES solution (both at  $\text{pH} = 4.3$ ), see Fig. S-21–S-24.† As a general observation, the data obtained is in good agreement with the UV/vis/NIR and EPR data for the same reaction conditions and the explanations given above.

### 3.3. Discussion of the main points of interest

**3.3.1. The use of hemin instead of HRPC.** Our investigations have shown that HRPC can be replaced by hemin for the synthesis of PANI-ES-like products using PADPA as monomer at an initial concentration of  $1.0 \text{ mM}$  (and  $1.0 \text{ mM}$   $\text{H}_2\text{O}_2$ ) in an aqueous solution containing SDBS micelles ( $5.0 \text{ mM}$  SDBS) at  $\text{pH} = 4.3$  ( $0.1 \text{ M}$  HEPES). High conversions of PADPA were

achieved within a reaction time of  $t = 24$  h at RT. All three complementary spectroscopic measurements used (UV/vis/NIR, EPR, and Raman spectroscopy), indicate that the products contain stable radicals that are typical for the conductive polaron state of PANI-ES (Fig. 1). However, due to the significantly lower catalytic activity of hemin as compared to HRPC, the molar amount of catalyst used in our experiments (10  $\mu$ M hemin) was significantly higher as compared to the concentration of HRPC (30 nM). Nevertheless, the costs for hemin to yield comparable PADPA conversions within a similar reaction time as with HRPC were only about 5% of the costs for HRPC, see ESI,† Section 6. An interesting topic of a possible follow-up investigation would be to explore whether hemin's catalytic activity could be increased by addition of electron-donating groups (*e.g.*, histidine or imidazole) at a concentration that optimizes peroxide coordination to Fe(III) of hemin. Although the basic form of hemin, hematin (= porFe<sup>III</sup>-OH), was used before as catalyst in aqueous micellar solutions of SDBS at  $T = 4$  °C for the synthesis of polypyrrole,<sup>69</sup> our work is the first one on the formation of poly(PADPA) products that resemble PANI-ES by using hemin as catalyst.

**3.3.2. The role of SDBS micelles.** There are two roles of SDBS micelles in the hemin-catalyzed formation of PANI-ES like products from PADPA: (i) the micelles prevent hemin aggregation, which enables hemin to be catalytically active, and (ii) the micelles serve as reaction “template”, *i.e.*, they guide the reaction towards the desired formation of the emeraldine salt form of PANI. Since for this latter role, which is directly related to the chosen reaction, the negative surface charge of the micelles is essential.<sup>9</sup> Whether other types of micelles (cationic, zwitterionic, or neutral) could be used as well for hemin-catalyzed reactions that do not rely on a “template” effect, remains to be investigated. In other words, one key question of interest is, whether there is a correlation between micelle type, capability to prevent hemin aggregation, and catalytic activity of hemin for (simple) reactions involving substrates that are different from PADPA and do not involve complex follow-up reactions that occur uncatalyzed after substrate oxidation as in the case of PADPA.

**3.3.3. The use of HEPES vs. dihydrogenphosphate.** In the hemin-catalyzed reactions investigated in this work, the use of HEPES proved to be more advantageous than the use of dihydrogenphosphate. Considering that the spectra of hemin in these two salt solutions look very similar in the presence of SDBS micelles (Fig. S-3†), one can conclude that in both systems the fraction of monomeric hemin is very similar. Therefore, the difference in the catalytic activity of hemin in the two micellar solutions is not due to different physical states of hemin (monomer,  $\pi$ - $\pi$  dimer, *etc.*). The difference more likely originates from different iron coordination propensities of the two salt species. It has already been shown that dihydrogenphosphate can displace water and bind to Fe(III) of hemin.<sup>70</sup> From the results we obtained, it appears that the binding of H<sub>2</sub>PO<sub>4</sub><sup>-</sup> is so strong that hydrogen peroxide is unable to displace the coordinated dihydrogenphosphate (or displaces it to a very low extent only), making the oxidation of hemin with H<sub>2</sub>O<sub>2</sub> to form compound I inefficient (Fig. S-10 and S-13†). On

the other hand, when HEPES was used, the impact of hydrogen peroxide was significant (Fig. 2 and S-12†). Therefore, we conclude that under the conditions used HEPES does not block the 5<sup>th</sup> and 6<sup>th</sup> coordination sites of Fe(III) as strong as dihydrogenphosphate does. In addition, HEPES species that are partially coordinated to Fe(III) may promote the reaction by either weak electron donation to the iron of hemin or by stabilizing a transition state.

**3.3.4. The role of H<sub>2</sub>O<sub>2</sub>.** As already stated in the Introduction, the aim of our work was to try to replace HRPC by its prosthetic group (ferric heme *b* = hemin). More specifically, we asked ourselves whether hemin can be used as peroxidase-mimic, as catalyst system in which hemin in SDBS micelles in the presence of H<sub>2</sub>O<sub>2</sub> follows the catalytic heme peroxidase cycle (Scheme S-1†), but in a less efficient manner. Although hemin proved to catalyze the formation of PANI-ES like material, it is by no means clear whether the observed reactions with hemin in the micellar system followed the same peroxidase cycle, with intermediate formation of compound I and compound II. Exploring the mechanism of the hemin/H<sub>2</sub>O<sub>2</sub>-catalyzed PADPA oxidation in the presence of SDBS micelles may be a challenge that could be addressed in a future study.

So far, important control measurements of reactions run without H<sub>2</sub>O<sub>2</sub> clearly demonstrated that the hemin-catalyzed formation of PANI-ES-like products from PADPA in 0.1 M HEPES solution at pH = 4.3 (in the presence of SDBS micelles) also occurs to some extent without H<sub>2</sub>O<sub>2</sub> (Fig. 2), although the reaction is much slower than with H<sub>2</sub>O<sub>2</sub> (Fig. 5 and S-12†). It seems that the oxidation of PADPA (or TMB) with hemin as catalyst occurs *via* two mechanisms, one involving H<sub>2</sub>O<sub>2</sub> as terminal oxidant, the other with O<sub>2</sub> (which was present in all reaction mixtures due to their exposure to air). Preliminary measurements with PADPA as substrate were carried out without H<sub>2</sub>O<sub>2</sub> under “oxygen-free” conditions (see Fig. S-25, S-26 and accompanying text for details†). The observation made is that in the absence of H<sub>2</sub>O<sub>2</sub> oxygen is necessary for the reaction to proceed. Although the mechanism involving oxygen is not clear at the moment and deserves further investigations, one possibility how the reaction might proceed is that Fe(III)PPIX is reduced to Fe(II)PPIX by PADPA, while at the same time PADPA is oxidized to the PADPA radical. Fe(II)PPIX is then reoxidized to Fe(III)PPIX by oxygen. Alternatively, the mechanism might be completely different, and it may include the formation of hydrogen peroxide *in situ*.<sup>71</sup>

## 4. Conclusion and outlook

The work carried out showed that hemin can be used successfully as catalyst for the oxidation of PADPA in a slightly acidic aqueous micellar solution of SDBS to yield products with PANI-ES structural units that are typical for the conductive form of polyaniline. Apart from applications of the products obtained, future studies may involve the investigation of the binding of hemin to the micelles, the use of other surfactant aggregates, or

† Heme Fe<sup>2+</sup> undergoes autooxidation in the presence of oxygen to Fe<sup>3+</sup>.<sup>79</sup>

an investigation of the reaction mechanism and a possible substrate selectivity. Beyond this, experimental proof of catalytically active hemin in aggregates of amphiphiles is also of interest for origin-of-life research. Porphyrins like PPIX are molecules that are not only ubiquitously present as prosthetic groups in contemporary proteins,<sup>72</sup> but may have been present already in prebiotic times.<sup>73,74</sup> Due to the likely prebiotic existence of simple membrane-forming amphiphiles,<sup>75</sup> these amphiphiles might have associated with metal porphyrins to form catalytically active assemblies for accelerating localized chemical transformations. In this way, amphiphile-heme aggregates could have served as a kind of “primitive enzymes”, even before the suggested heme RNA quadruplex systems possibly formed.<sup>76</sup> Although this is pure speculation, the idea is worth considering in scenarios on the prebiological emergence of functional compartment systems, in steps that preceded the first living cells at the origin of life on earth.<sup>77</sup>
