Intrahepatic cholangiocarcinoma is a rare malignancy that originates from the epithelial cells of the intrahepatic bile ducts. Intrahepatic cholangiocarcinoma can metastasize in lymphatic chains, including the hepatoduodenal ligament, and it often invades adjacent organs or metastasizes to other visceral organs such as the lungs, bones, adrenal glands, and brain. However, distant skeletal muscle metastasis is very rare. Moreover, a metastatic skeletal muscle tumor rarely shows specific symptoms, making it difficult to identify in a routine examination. A 45-year-old man with a chief complaint of right upper quadrant abdominal pain was admitted to our hospital. Abdominal ultrasound and computed tomography with contrast enhancement showed a malignant mass in the right hepatic lobe, and 2-[^{18}F] fluoro-2-deoxy-D-glucose positron-emission tomography revealed distant skeletal muscle metastases in the thorax and buttock. The patient underwent an ultrasound-guided percutaneous needle biopsy for the metastatic low-echo masses in the skeletal muscle. ([Korean J Hepatol 2010;16:325-328](#))

Keywords: Intrahepatic cholangiocarcinoma; Distant metastasis; ^{18}F -FDG PET

INTRODUCTION

Cholangiocarcinomas arise from the epithelial cells of the bile ducts in the intrahepatic, perihilar, or distal (extrahepatic) biliary tree, and are exclusive of the gallbladder and ampulla of Vater. Common symptoms include pruritus, abdominal pain, weight loss, and fever. Intrahepatic cholangiocarcinomas originate peripherally within the intrahepatic ducts of the liver parenchyma, and form 5~10% of cholangiocarcinomas.^{1,2} Imaging studies are essential for the diagnosis of cholangiocarcinoma. Transabdominal ultrasound, contrast-enhanced, triple phase, and helical computed tomography, magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, and percutaneous transhepatic cholangiopancreatography have been used to diagnose cholangiocarcinoma. Tumor markers such as carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA) can be useful in conjunction with biopsy or brushings to confirm the

diagnosis. It is often difficult to make a definite diagnosis of cholangiocarcinoma preoperatively. Ultrasound or CT-guided percutaneous biopsy should be considered to confirm. ^{18}F -fluoro-2-deoxy-D-glucose positron emission tomography is also useful for detecting lymph node metastasis, distant metastasis, and a recurrence of intrahepatic cholangiocarcinoma.³

A complete surgical resection is the only curative treatment for cholangiocarcinoma.² Patients who have unresectable disease may need palliative therapies, such as surgical or endoscopic biliary drainage, chemotherapy, radiation therapy, or stenting.⁴ Intrahepatic cholangiocarcinomas often invade adjacent organs or metastasize to other visceral organs. However, skeletal muscle metastasis from cholangiocarcinoma is very rare. This report describes a case of skeletal muscle metastasis from an intrahepatic cholangiocarcinoma as the first distant metastasis that was identified on 2-[^{18}F] fluoro-2-deoxy-D-glucose positron emission tomography (^{18}F -FDG PET) during the initial work up.

CASE REPORT

A 45-year-old man was admitted to Department of Gastroenterology because of abdominal pain. An ultrasound report from another hospital showed a mixed echoic mass in hepatic segments VII and VIII that measured about 4.3×3.0 cm in diameter. About 10 years ago, he had taken renal biopsy due to proteinuria, however, the biopsy findings revealed no specific disease. He denied tobacco and alcohol use.

On physical examination, the patient was not icteric, but had right upper quadrant abdominal tenderness. Laboratory findings taken on admission were as follows: Hb 12.2 g/dl, WBC $5.8 \times 10^3/\mu\text{l}$, platelets $164 \times 10^3/\mu\text{l}$, urea nitrogen 34.0 mg/dl, creatinine 3.6 mg/dl, aspartate aminotransaminase 22 IU/l, alanine aminotransaminase 15 IU/l, total bilirubin 0.37 mg/dl, amylase 183 IU/l, lipase 140 IU/l, HBsAg negative, anti-HCV negative, rapid plasma reagin non-reactive, alpha-fetoprotein 1.7

Figure 1. Abdominal computed tomography (CT) findings. An ill-defined low-density lesion with peripheral intrahepatic duct dilatation (A, C). Lymph node metastases were evident at the hepatoduodenal, aortocaval, and left para-aortic areas (B).

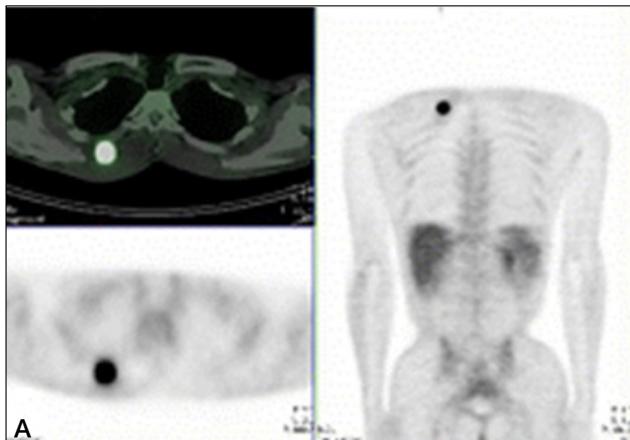

Figure 2. Positron-emission tomography-computed tomography (PET-CT) findings. Soft-tissue metastasis was present in the right thoracic back (p-SUV=8.9) (A), and the left buttock (p-SUV=4.5) (B).

ng/mg, PIVKA II 23 mAU/ml, CA19-9 574.8 U/ml. A 24-hour urinary protein excretion was 1,498 mg/day.

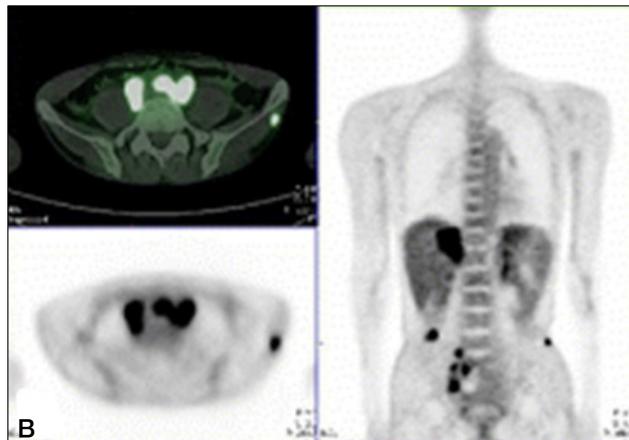

A contrast-enhanced CT of the liver showed a low-density mass in hepatic segments VII and VIII and enhanced lymph nodes, including the hepatoduodenal ligament and aortocaval and left para-aortic region, as well as a small amount of ascites in the early arterial phase (Fig. 1). A peripherally enhanced, low-density mass was revealed in the delayed phase. Intrahepatic cholangiocarcinoma was diagnosed based on the CT findings. He underwent ^{18}F -FDG PET, which showed a malignant mass in the right hepatic lobe (p-SUV=11.2), a metastasis to the retroperitoneal and right common iliac lymphatic chain, and a distal paraesophageal area around the celiac axis. A paraspinal muscle metastasis in the right thoracic back (p-SUV=8.9) and left gluteus minimus muscle metastasis (p-SUV=4.5) were also revealed (Fig. 2).

An ultrasound-guided percutaneous needle biopsy of the low echoic mass was performed at the left buttock area near the left iliac crest (Fig. 3). The pathologic findings revealed an adenocarcinoma that was positive for cytokeratin 7 and 19 but negative for cytokeratin 20 and CEA (Fig. 4).

The abdominal CT, ^{18}F -FDG PET findings, and histopathologic features were compatible with intrahepatic cholangiocarcinoma with a distant skeletal muscle metastasis.

DISCUSSION

Biliary tract cancers are divided into cancers of the gall bladder, extrahepatic ducts, and the ampulla of Vater, and intrahepatic biliary tumors are classified as primary liver cancers.¹ Intrahepatic cholangiocarcinoma is a malignant tumor arising

from the epithelial cells of the intrahepatic bile ducts. Intrahepatic cholangiocarcinomas initially present as mass-forming lesions, and obstructive symptoms are rare.⁴ Fever, night sweats, and weight loss may occur in addition to right upper quadrant abdominal pain.⁴ Without clear reasons, the incidence of intrahepatic cholangiocarcinoma has been increasing over the past two decades in Europe, North America, Asia, Japan, and Australia.⁵ Some of this may be attributable to new diagnostic methods identifying biliary malignancies that have previously not been diagnosed.⁶

The major metastatic pattern for intrahepatic cholangiocarcinomas is early lymphatic spread. The hepatoduodenal ligament is the most common site for lymph node metastasis irrespective of tumor location. In the majority of cases, intrahepatic cholangiocarcinomas involve the lymph nodes of the hepatoduodenal ligament or those along the common hepatic artery.^{7,8} Cholangiocarcinomas have often metastasized to distant organs, and ¹⁸F-FDG PET is of value in discovering unsuspected distant metastases of cholangiocarcinoma.^{3,9} Other investigators showed that nine distant metastatic lesions were detected by ¹⁸F-FDG

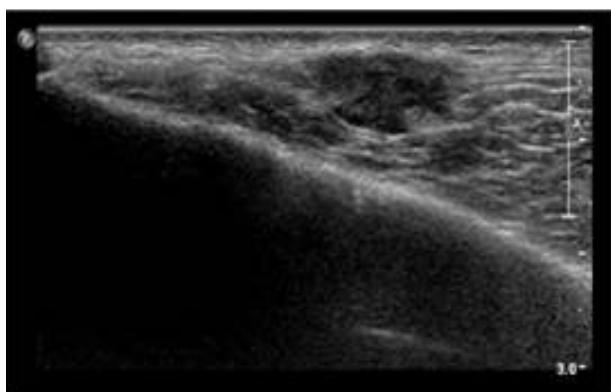

Figure 3. Ultrasonography image of the left buttock area. A low-echo mass lesion in a muscle layer was evident around the left iliac crest ($0.5 \times 1 \text{ cm}^2$).

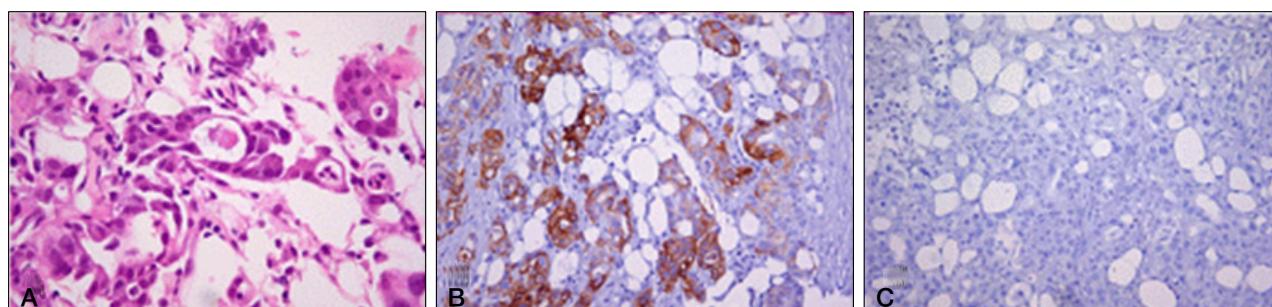

Figure 4. Microscopic findings of a muscle biopsy. Neoplastic glandular infiltration was present in the skeletal muscle, suggesting metastatic adenocarcinoma (hematoxylin and eosin, $\times 200$) (A). Neoplastic glands were positive in cytokeratin 7 immunostaining ($\times 200$) (B), and negative in cytokeratin 20 staining ($\times 200$) (C).

PET that were not detected using other imaging modalities.¹⁰ Because surgical resection is the only curative treatment of intrahepatic cholangiocarcinoma, accurate staging with ¹⁸F-FDG PET is useful for appropriate management.

Although skeletal muscle accounts for approximately 50% of the total body mass and receives a large volume of blood, distant skeletal muscle metastasis is very rare.¹¹ The reason is not well elucidated. The effect of lactic acid on tumor cell production,¹² the influence of variable and turbulent blood flow, β -adrenergic stimulation, tissue oxygen levels, and host immune response may provide protective mechanisms to skeletal muscle.¹³ Moreover, protease inhibitors in the muscle extracellular matrix may resist cancer cell invasion.¹⁴

Skeletal muscle metastasis is not generally explored until patients complain of symptoms such as localized pain or a palpable mass. Besides, intrahepatic cholangiocarcinomas are highly lethal, as most are locally advanced at presentation. This might be why distant skeletal muscle metastases from intrahepatic cholangiocarcinomas are rarely reported.

In our case, asymptomatic skeletal muscle metastasis was diagnosed by ¹⁸F-FDG PET during the initial examination in the patients with intrahepatic cholangiocarcinoma.
