### Abstract

**Background:** *RAD54L* (OMIM 603615, Locus Link 8438) has been proposed as a candidate oncosuppressor in tumours bearing a non-random deletion of 1p32, such as breast or colon carcinomas, lymphomas and meningiomas. In a search for *RAD54L* mutations in 29 meningiomas with allelic deletions in 1p, the only genetic change observed was a silent C/T transition at nucleotide 2290 in exon 18. In this communication the possible association of the 2290C/T polymorphism with the risk of meningiomas was examined. In addition, the usefulness of this polymorphism as a genetic marker within the meningioma consensus deletion region in 1p32 was also verified. The present study comprises 287 blood control samples and 70 meningiomas from Spain and Ecuador. Matched blood samples were only available from Spanish patients.

**Results:** The frequency of the rare allele-T and heterozygotes for the 2290C/T polymorphism in the blood of Spanish meningioma patients and in the Ecuadorian meningioma tumours was higher than in the control population ( $P < 0.05$ ). Four other rare variants (2290C/G, 2299C/G, 2313G/A, 2344A/G) were found within 50 bp at the 3' end of *RAD54L*. Frequent loss of heterozygosity for the 2290C/T SNP in meningiomas allowed to further narrow the 1p32 consensus region of deletion in meningiomas to either 2.08 Mbp – within DIS2713 (44.35 Mbp) and *RAD54L* (46.43 Mbp) – or to 1.47 Mbp – within *RAD54L* and DIS2134 (47.90 Mbp) – according to recent gene mapping results.

**Conclusion:** The statistical analysis of genotypes at the 2290C/T polymorphism suggest an association between the rare T allele and the development of meningeal tumours. This polymorphism can be used as a genetic marker inside the consensus deletion region at 1p32 in meningiomas.

### Background

Meningiomas are slow-growing tumours derived from the arachnoid membrane surrounding the central nervous system. They are one of the commonest intracranial tu-

mours, accounting for 20% of all brain tumours, with an overall incidence of 2.3/100,000 and a 2:1 female-to-male ratio [1]. The frequent finding of asymptomatic meningiomas in computerised tomography and magnetic

resonance studies [2] will probably raise these prevalence figures. A close relationship exists between meningiomas and neurofibromatosis type II (NF2). Meningiomas have been found in more than 50% of patients with this common hereditary disorder and sporadic meningiomas show frequent mutations in the NF2 oncosuppressor gene [3–5]. Besides NF2, other candidate genes are suspected to be involved in the multistep development of meningiomas; among these genes are those presumably inactivated by deletion/mutation in 1p32, a region of frequent loss of heterozygosity (LOH) in sporadic and hereditary meningiomas [4,6–9]. Mapped at 1p32 and with likely functions in mitotic and meiotic recombination, RAD54L (OMIM 603615, Locus Link 8438), a member of the SNF2/SWI2 family of DNA-dependent ATPases, has been proposed as a candidate oncosuppressor in breast tumours [10]. The finding of mutations in a small fraction of breast carcinomas (1 out of 95 tumours), colon carcinomas (1 out of 13 tumours) and lymphomas (1 out of 24) supports the involvement of RAD54L in tumorigenesis [11].

In a previous single strand conformation polymorphism (SSCP) analysis of 29 meningiomas with 1 p deletions we failed to detect any mutation in the *RAD54 L* gene, but found instead a silent C/T polymorphism (Ala730Ala) that was identified by direct sequencing of PCR-amplified exons [12]. This polymorphism has been independently identified (NCB SNP cluster ID: rs1048771) in chromosome 1 contig NT\_004386 using high output methods for SNP detection. Blast analysis has unequivocally linked the variation to nucleotide 2290 of *RAD54L* mRNA (Gen Bank accession X97795.1) or to nucleotide position 2851 in the NCBI RefSeq (accession NM\_003579.2); however, lack of information regarding population genotype and allele frequency has precluded its validation as an SNP marker. In this communication the possible association of 2290C/T polymorphism with the risk of meningiomas was examined. In addition, the usefulness of this polymorphism as a genetic marker within the meningioma consensus deletion region in 1p32 [6] was also ascertained.

## Methods

### Tissue samples

Twenty-nine Spanish tumours with deletions in 1p and matched blood samples were obtained from meningioma patients as previously described [5,12]. Forty-one paraffin archival, randomly-chosen, samples of meningiomas (20 meningothelial, 11 transitional, 5 fibroblastic, 3 psammatose and 2 angioblastic) were obtained from the pathology services of *E. Espejo* and *C. Andrade Marín* hospitals in Quito, Ecuador. Two of them were grade II and 39 grade I, according the WHO Classification. No matched blood samples from those patients were availa-

ble. Spanish and Ecuadorian blood control were obtained from healthy transfusion blood donors.

### DNA extraction

Genomic DNA was prepared from frozen tissues by standard methods previously described [5,12]. DNA from paraffin-embedded samples was extracted by standardised protocols [13]. DNA from peripheral lymphocytes was extracted using a DNA-extraction kit from Stratagene, according to the manufacturer's protocol.

### PCR based analysis of RAD54L polymorphism and 1p polymorphic markers

The allelic status of 2290 C/T polymorphism in tumour and blood samples was ascertained by PCR amplification of exon 18 followed by SSCP analysis as described [12]. On some occasions confirmatory direct sequencing analysis of PCR products was carried out as described [12]. The allelic status at microsatellite loci was analysed as described [5,12].

### Statistical analysis

Epidemiological variables and genotypes were evaluated using Tukey-Kramer comparison tests, Odds ratios and Fisher's two-sided exact test.

## Results and discussion

In order to validate the SNP status of the 2290 C/T polymorphism we have extended our previous observations with the analysis of additional Spanish control population (up to 87 healthy blood donors) and have also included a new control group of 149 healthy blood donors and 41 meningioma samples from Ecuador. In Table 1 we summarise the epidemiological data of the patients included in this study. The sex ratio in both Ecuadorian and Spanish patients (2.7 and 3.1 female/male ratio, respectively) is higher than that reported for larger populations. The age at diagnostic is similar in the Ecuadorian sex groups and in the Spanish male patients, but is higher in the Spanish female group. Marked differences were also observed in tumour histopathology. While most of the Ecuadorian meningiomas were of WHO grade I, the Spanish tumours were of a predominant grade II-III histology. These dissimilarities originate from the selection criterion used in selecting meningioma patients – random in Ecuador, LOH for 1p markers in Spain – and the well established correlation between 1p loss and meningioma progression [5,6].

As shown in Table 2, heterozygotes and T-allele frequencies were statistically indistinguishable in control population groups from Ecuador and. In both cases the results conform to the Hardy and Weinberg equation. We have also measured allele frequencies for the *RAD54L* 2290 C/T polymorphism in meningioma patients from Spain and

Ecuador. The Spanish group included 29 tumour samples with 22 matched peripheral blood samples from a subset of patients with LOH for at least one marker of chromosome 1p and prevailing atypical/anaplastic histology (see Table 1) as previously reported [5]. Heterozygosity and T-allele frequencies were higher in the lymphocyte DNA from Spanish patients ( $P = 0.0036$  and  $0.0037$ , respectively) as compared with the Spanish control population. The heterozygosity in the Spanish meningeal tumours (0.069) was much lower than in the patient's peripheral blood (0.500) and in Ecuadorian tumours (0.732). This discrepancy is an expected consequence of the selection criterion for the Spanish meningioma (LOH for at least one marker of 1p) and the frequent loss of heterozygosity (9/11 informative cases, 82%) observed for the 2290C/T polymorphism in this tumour group. The frequency of the rare T-allele (0.22) in the Spanish meningioma group is similar to the patient's blood and higher than in the healthy controls. Similar frequency has been reported in a mutational study of several tumour samples [11]. The meningeal tumours from Ecuador, consisting of 41 archival paraffin samples with a predominant WHO grade I histology (see Table 1) showed (Figure 1 and Table 2) a very high rate of heterozygosity, amounting to 73% of this group versus 20% in the control Ecuadorian population. Although the predominantly typical histology would suggest a low incidence of 1p deletions [5,6] in these tumour samples, the unavailability of blood from Ecuadorian patients prevented the ascertainment of LOH and hemizyosity in the tumour samples and, as a result, the frequency of the C-allele was probably overestimated. Even with this drawback, the frequency of heterozygosity and T-alleles was very high and extremely significant when compared with the

Ecuadorian control population ( $P = 0.0001$ ). The similarity between Ecuadorian tumours and the constitutive Spanish patients genotypes, with higher heterozygosity and T-allele frequency than their healthy population controls are noteworthy, and suggest the presence of an association between the 2290T-allele and the development of meningeal tumours.

Besides the 2290C/T polymorphism, other rare variants were found at the 3' end of *RAD54L* exon 18, as summarised in Figure 2, together with the mismatches (boxes 1, 4 and 5 in the figure) between genomic and mRNA sequences already reported in the NCBI database (Evidence View, graphic display option) when searched for *RAD54L*. Besides the 2290C/T polymorphism, a new silent 2290C/G variant (box 1–2 in Figure 2) has been found in 1 out of the 11 sequenced Ecuadorian meningeal tumours. Another new 2299C/G, F733L variant (box 3 in Figure 2) has been found with a low frequency (1/11) in Ecuadorian tumours. The 2313G/A, R738H variant (box 4 in the figure 2) has already been reported as a mismatch. Finally, a new 2344A/G variation (box 6 in Figure 2) replaces the 747-stop codon with a tryptophan and displaced the protein termination signal to the next TAA codon in position 748. This variation has been found in the Ecuadorian (1/11) and Spanish (1/13) samples. The high density of variations found in exon 18 (5 in 52 nucleotides) is noteworthy and suggests the occurrence of a genomic instability at the 3' end of *RAD54L*.

The high frequency of constitutional heterozygosity in the 2290C/T alleles found in a subset of meningioma patients with deletions in the short arm of chromosome 1 (Table

**Figure 2**  
**Variants and mismatches in exon 18 of RAD54L and molecular linkage of RAD54L and MUF1 through an inverse overlapping of untranslated mRNA.** In the upper side of the figure, variants found in meningiomas (numbered 1–2, 3, 4, 5 and 6) and mismatches reported in the NCBI (Evidence Viewer, graphic display for RAD54L) (1, 4 and 5) are shown in bold within green boxes. The figure displays from top to bottom: the reference protein (Rp) and mRNA (Rs) at the 3' end of RAD54L, the variants and mismatches (Vr) and their corresponding protein sequences (Vp). In the lower part of the figure the inverse overlapping 70 bp sequence shared by RAD54L and MUF1 3'UTR is shown. Figures in brackets correspond to nucleotide positions in the NT\_004386 contig.

1) together with the frequent loss of heterozygosity for the 2290C/T alleles in the Spanish meningeal tumours (82% of the informative cases), suggests that this SNP could be used as a 1p32 marker inside the critical 1.5 cM consensus deletion region in meningiomas [6]. Using our own published [5,12] and unpublished (Mendiola. Chemistry MS thesis, UAM, Madrid, 1999) data, together with recent information on the sequence map for chromosome 1 (available through the web of the NCBI, Entrez Genome and UniSTS, updated as of September 2002), we were able to identify 2 tumour samples (numbers 13 and 14 in figure 3) in which the LOH for the 2290C/T SNP marker further reduced the 1p32 consensus region for deletion in meni-

giomas (3.55 Mbp) within D1S2713 (44.35 Mpb) and D1S2134 (47.90 Mbp), to either the 2.08 Mbp between D1S2713 and RAD54L (46.43 Mpb) or the 1.47 Mbp between RAD54L and D1S2134 (see Figure 3). This narrowed definition of the minimal region of allelic loss excludes candidate genes telomeric to D1S211 (44.07 Mbp), such as GROS1 [15], mapped at 43.3 Mbp, or genes centromeric to D1S197 (51,70 Mbp), such as CDKN2C [16]. The exclusion of CDKN2C as a candidate oncosuppressor in meningiomas has also been suggested in recent molecular studies [9]. TAL1 [17] and SIL [18], which map at 50.20 Mbp within the consensus deletion region (Figure 3), have proto-oncogen functions in leukaemia, and

**Figure 3**

**Summary of LOH analysis and map information.** A. Sequence maps of 1p markers and genes were obtained from NCBI gene maps and UniSTS records (updated as of September 2002). Salmon coloured horizontal lines delimit the smallest overlapping region flanked by DIS2713 and DIS2134 [6]. LOH results for 11 *RAD54L* polymorphism informative cases are taken from previous published and unpublished results (see the text). Open and closed circles correspond to retention and loss of heterozygosity respectively. The horizontal bar represents uninformative constitutional homozygosity. Patient identification as in ref. 5. B. SSCP of constitutive (C) and tumoral (T) DNA from patients 13 and 14, showing LOH of *RAD54L* and retention of heterozygosity for DIS197 and DIS232 markers.

are unlikely oncosuppressor candidates. Besides *RAD54L*, other oncosuppressor candidates mapping within the smallest region of overlap (D1S2713-*RAD54L*) are *PTCH2*, *MUTYH* and *MUF1*. *PTCH2* (OMIM 603673, Locus Link 8643), the human homologue of *Drosophila* patched-hedgehog, has been implicated in malignancies such as medulloblastoma and basal cell carcinoma [19]. *MUTYH* (OMIM 604933, Locus Link 4595), a homologue of the yeast *mutY* gene, is an oxidative mismatch repair protein [20] which could be involved with *MUTL* in susceptibility to hereditary nonpolyposis colon cancer (HNPCC, OMIM 120535). *MUF1* (Locus Link 10489) has recently been characterised as an Elongin BC-interacting protein, akin to the Von Hippel Landau (*VHL*) tumour suppressor protein in its ability to assemble with Cul5 and Rbx1 and reconstitute a ubiquitin ligase [21]. To our knowledge none of these putative candidate genes has been studied in meningiomas.

The statistical association between the rare T allele in the 2290C/T polymorphism and the risk of meningioma development (Table 1) requires some attention. It is unlikely that the 2290C/T silent variation (Ala730Ala) could result in functionally different alleles, and there is no evidence for any plausible effect on mRNA transcription. Alternatively, it is possible that the T-allele is in linkage disequilibrium with another sequence of DNA directly implicated in tumour development. According to the draft chromosome 1 sequence (accession NT\_004386, in Entrez Nucleotide from NCBI web), *RAD54L* and *MUF1* share 69 bp of a convergent and inverted untranslated mRNA that contains the poly (A+) signal and the site for polyadenylation for both genes (Figure 2). This is a condition for dsRNA production that could initiate a chain reaction of gene silencing through degradation of homologous messenger RNA molecules [22,23]. Whether the 2290T-allele is actually linked to a gene silencing mechanism through homologous antisense dsRNA of either the *RAD54L* mRNA or *MUF1* mRNA would require elucidation in further studies, which also have to consider the genomic instability observed at the 3' end of *RAD54L*.

## Conclusions

The statistical analysis of genotype (2290C/T) distribution among meningioma patients and healthy controls suggests that the rare T allele is associated with the risk of meningioma development. In addition, this study also shows that the 2290C/T variation can successfully be exploited as a polymorphic marker inside the consensus deletion at 1p32 in meningiomas.

## List of abbreviations

PCR (polymerase chain reaction), SSCP (single stranded chain polymorphism), LOH (loss of heterozygosity), SNP (single nucleotide polymorphism)

## Competing interests

None declared.

## Authors' contributions

PEL and CPM processed and analyzed tissue and blood samples from Ecuador. MM and JA processed the Spanish samples. AP coordinated the study and drafted the manuscript.

## Web links

Entrez <http://www.ncbi.nlm.nih.gov/Entrez> is the NCBI common retrieval system for SNP, UniSTS, OMIM, nucleotide, genome and other databases.

LocusLink <http://www.ncbi.nlm.nih.gov/LocusLink> is the NCBI interface for search curated sequences and information about genetic loci.
