ABSTRACT

Background More than a quarter of the UK population are affected by depression during their lifetime. For major trauma patients, postinjury depression can result in poorer long-term outcomes, but there is limited evidence regarding outcomes for patients with pre-existing depression. This study investigated the relationship between a diagnosis of depression prior to hospital admission and clinical outcomes after major trauma.

Methods Trauma patients at a UK major trauma center were identified during a 6.5-year period using the Trauma Audit and Research Network database. Patients with Injury Severity Score >15 who did not die in the emergency department (ED) were included. Logistic regression models were used to compare in-hospital mortality (excluding ED), requirement for surgery, and length of stay (LOS) between those with depression and those without.

Results There were 4602 patients included in the study and 6.45% had a diagnosis of depression. Depression was associated with a significant reduction in mortality (OR 0.54, 95% CI 0.30 to 0.91; $p=0.026$). However, patients with depression were more likely to have longer LOS (OR 124, 95% CI 8.5 to 1831; $p<0.001$) and intensive care unit LOS (OR 9.69, 95% CI 3.14 to 29.9; $p<0.001$). Patients with depression were also more likely to undergo surgery (OR 1.36, 95% CI 1.06 to 1.75; $p=0.016$).

Discussion A pre-existing diagnosis of depression has complex association with clinical outcomes after major trauma, with reduced mortality but longer LOS and higher likelihood of surgical intervention. Further prospective investigations are warranted to inform optimal management strategies for major trauma patients with pre-existing depression.

Level of evidence III.

INTRODUCTION

Depression is the most commonly diagnosed mental health condition and is a leading cause of global morbidity.¹ In the UK, over a quarter of the population will at some point be affected by depression,² and there is an estimated prevalence of 11%.³ More recently, the proportion of people experiencing depression has been exacerbated by the global COVID-19 pandemic, with a systematic review reporting a global prevalence of 33.7% during the study period up until May 2020.⁴ Similarly, the UK Office for National Statistics reported that 19.2% of adults exhibited symptoms of depression during June 2020.⁵ Considering the current

increase in depression, it is essential to understand how depression might impact on patient outcomes after injury.

Depression is a well-documented adverse outcome after major trauma which can result in significant disability and reduced quality of life.^{6–10} Efforts have been made to mitigate the risk factors which lead to postinjury depression.^{11–13} However, there is a relative sparsity of evidence regarding preinjury depression and its relationship with in-hospital outcomes after major trauma. There are suggestions that major trauma patients with depression have worse postoperative complications,¹⁴ and that there may be associations with in-hospital outcomes such as mortality and length of stay (LOS), but most studies have not looked at major trauma.^{15–20} Therefore, specific studies of the major trauma population are warranted because they are likely to have different outcomes and care requirements compared with those suffering minor trauma, and risk factors are not always applicable to both groups.²¹ Although studies have investigated the impact of any mental health difficulties as a whole on the outcomes after injury,^{22,23} it cannot be assumed that all mental health difficulties will affect in-hospital outcomes in the same way.

There are conflicting reports in the literature regarding whether depression is a risk factor for in-hospital mortality in any subset of trauma patients. Whereas one study among the general trauma population suggested that depression is a risk factor for mortality,¹⁸ two further studies in orthopedic trauma populations demonstrated a reduction in mortality among patients with depression.^{17,20} Due to this uncertainty, an examination of a large population of major trauma patients is warranted.

The current study aimed to investigate the relationship between a pre-existing diagnosis of depression and clinical outcomes in patients after major trauma. We hypothesized that patients with depression were more likely to have poorer clinical outcomes overall.

METHODS

Study design

A retrospective observational study was undertaken using the prospectively recorded Trauma Audit and Research Network (TARN) database for a single major trauma center (MTC) in the West Midlands (University Hospitals Birmingham NHS Foundation Trust).

Patient selection

Data were requested from the TARN database for all trauma patients at the University Hospitals Birmingham NHS Foundation Trust's MTC admitted between January 1, 2014 and July 31, 2020 with an Injury Severity Score (ISS) greater than 15. The TARN database includes patients who fulfill certain LOS criteria and must have at least one of the following: ≥ 3 overnight stays in hospital, critical care admission, hospital transfer or repatriation where there is a total of ≥ 3 overnight stays, or death.²⁴ For the current study, patients from the database who died in the emergency department (ED) or who had insufficient data for the study criteria were excluded (n=121).

Data collection

The following data were extracted from the TARN database: patient demographics (including medical history and medication history, age and gender), injury characteristics at admission (ISS, regional Abbreviated Injury Scale (AIS) score, Glasgow Coma Scale (GCS) score), and clinical outcome data. A Charlson Comorbidity Index (CCI) score was created from patients' documented medical history.²⁵ Electronic records were also searched for confirmation of data acquired from TARN.

A history of depression, irrespective of treatment, has been identified as a risk factor in previous study populations.^{16 18 19} Therefore, data on treatment were not collected in the current study, and patients were categorized as having a pre-existing diagnosis of depression if they had a recorded history of depression within the TARN database. Medical history is a compulsory field within the TARN database; a pre-existing diagnosis of depression is recorded when a clinician has documented a medical history of depression in a patient's clinical noting. Anonymized data were collated and stored on an encrypted National Health Service (NHS) computer database.

Clinical outcomes

The outcomes of interest in the current study were taken directly from the TARN data and included in-hospital mortality (excluding ED), LOS, LOS in the intensive care unit (ICU), ICU admission, requirement for surgery, and number of operations.

Data analysis

Data are presented as number and percentage for categorical data and median and IQR for continuous data. Fisher's exact test and χ^2 test were used for comparison of categorical data as appropriate, and Mann-Whitney U test was used to compare continuous data. Logistic regression models were used to determine the OR and 95% CI for each clinical outcome using a pre-existing diagnosis of depression as an independent variable. The other independent variables in the models were chosen a priori as clinically relevant factors and included age, gender, ISS, GCS score, and CCI. A p value of <0.05 was considered statistically significant. Statistical analysis and graph generation were performed using GraphPad Prism V.9.1.0 (GraphPad Software, San Diego, California, United States of America) and R (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Patient and injury characteristics

There were 4723 major trauma patients identified during the study period, and after exclusions this gave a study cohort of 4602 included patients. The median age of the total study population was 55 (IQR 34–76) years and 72.9% were male. Patients with pre-existing depression accounted for 297 of 4602 (6.45%)

Table 1 Patient demographics and injury characteristics at baseline

Baseline characteristics	No depression (n=4305)	Pre-existing depression (n=297)	P value
Age, median (IQR) years	56 (33–76)	51 (38–67)	0.015*

patients in the study cohort. There was a median CCI of 1 (IQR 0–4). The median ISS was 25 (IQR 18–29) and the median GCS score was 15 (IQR 12–15).

Patient characteristics were compared between those with depression and those without depression in table 1. Patients with depression were significantly more likely to be younger (median age: 51 (IQR 38–67) years vs. 56 (IQR 33–76) years; $p=0.015$) and female (44% vs. 37%; $p=0.005$) and were less likely to have significant comorbidities (median CCI: 1 (IQR 0–4) vs. 1 (IQR 0–3); $p=0.001$). Whereas differences existed in patient demographics, there were no significant differences in injury characteristics at baseline (table 1).

Univariate analysis

Overall, the absolute risk of mortality was 0.126 (95% CI 0.117 to 0.136). In total, 50.5% of patients were admitted to ICU and the median ICU LOS was 1 (IQR 0–5) day, whereas the median hospital LOS was 13 (IQR 6–26) days. Surgical intervention was performed for 51.9% of patients and the median number of operations was 1 (IQR 0–1). Before adjusting for baseline characteristics, depression was associated with increased LOS and ICU LOS, but a decrease in mortality (table 2 and figure 1).

Table 2 Association of depression with mortality, ICU admission, LOS, ICU LOS, and surgical intervention before adjustment for confounding factors

Outcome	No depression (n=4305)	Pre-existing depression (n=297)	P value
Mortality, n (%)	562 (13)	20 (7)	0.001*
ICU admission, n (%)	2162 (50)	160 (54)	0.231
LOS, median (IQR) days

ICU, intensive care unit; LOS, length of stay.

Multivariate analysis

Mortality

Using the logistic regression model, it was determined that increased age, CCI, ISS, and reduced GCS score were all significantly associated with increased mortality (table 3). However, among patients with a history of depression, there was a statistically significant reduction in mortality (OR 0.54, 95% CI 0.30 to 0.91; p=0.026).

Hospital and ICU episodes

Figure 2 demonstrates the monthly hospital and ICU admissions for major trauma patients throughout the study period. Longer hospital and ICU LOS were associated with increased ISS and age and reduced GCS score (table 4). Male gender was associated with prolonged ICU LOS but not in-hospital LOS, and a higher CCI was associated with a reduction in ICU LOS (table 4). Depression was not found to be a risk factor for admission to ICU (OR 1.09, 95% CI 0.94 to 1.23; p=0.311). However, depression was associated with a significantly longer ICU LOS (OR 9.69, 95% CI 3.14 to 29.9; p<0.001). Similarly, depression was strongly associated with longer in-hospital LOS (OR 124, 95% CI 8.5 to 1831; p<0.001).

Figure 1 Mortality, admission to intensive care unit (ICU), and operative intervention compared between those with and without a pre-existing diagnosis of depression.

Table 3 Associations of baseline characteristics with mortality in the regression analysis

Baseline characteristics	OR	95% CI	P value
Pre-existing depression	0.54	0.30 to 0.91	0.026*
CCI	1.21	1.10 to 1.34	<0.001*
Age	1.04	1.03 to 1.05	<0.001*
Male gender	1.14	0.89 to 1.45	0.303
ISS	1.04	1.03 to 1.05	<0.001*
GCS score	0.74	0.72 to 0.76	<0.001*

Operative intervention

Patients with depression were significantly more likely to undergo surgical intervention (OR 1.36, 95% CI 1.06 to 1.75; p=0.016), and operative intervention was also more likely in younger and in male patients with higher ISS and higher GCS score (table 5).

DISCUSSION

To our knowledge, this study is the first to investigate the relationship between pre-existing depression and mortality, LOS, ICU LOS, or operative intervention after major trauma, as defined by ISS >15. A history of depression was associated with a reduced OR for mortality in our study, which matched for comorbidities, age, gender, injury severity, and GCS score. However, depression was associated with significantly longer stay in hospital and ICU.

Our data are in contrast to studies in non-trauma populations which generally associate depression with increased mortality.²⁶ However, two studies of orthopedic trauma patients have also reported reduced mortality in patients with depression.^{17,20} Our LOS findings are in keeping with prior evidence that identified depression as a risk factor for LOS and ICU LOS.^{15–17,19} Increased LOS in hospital and ICU may reflect impaired functional recovery, which is also in keeping with previous reports that patients who develop depression after injuries have impaired long-term functional recovery.^{7,27} Since long ICU stays may be associated with increased complication rates,²⁸ and poorer long-term morbidity and mortality,²⁹ a history of depression should serve as an important prognostic indicator and might alert

Figure 2 Monthly hospital and intensive care unit (ICU) admissions for major trauma patients during the study period.

Table 4 Association of baseline characteristics with LOS and ICU LOS in the regression analysis

Baseline characteristics	Admission to ICU OR, 95% CI; p value	ICU LOS OR, 95% CI; p value	In-hospital LOS OR, 95% CI; p value
Pre-existing depression	1.09, 0.94 to 1.23; 0.311	9.69, 3.14 to 29.9; 0.001*	124, 8.5 to 1831; 0.001*
CCI	0.79, 0.73 to 0.85; <0.001*	0.49, 0.36 to 0.65; <0.001*	0.65, 0.33 to 1.30; 0.224

clinicians to anticipate the requirement for additional support with rehabilitation.

Depression is also associated with increased perception of pain,³⁰ which may impair patients' ability to mobilize and engage with physical therapy,³¹ possibly contributing to this impaired functional recovery and delayed discharge.^{31,32} There is also evidence that patients with depression are more likely to have poorer health behaviors, such as smoking and physical inactivity,³³ which may predispose them to complications and increased LOS.³⁴ Thus, the influence of pain perception and health behaviors on the functional recovery of trauma patients with depression warrants further investigation.

It is common for trauma patients to develop new depressive symptoms when admitted to ICU,³⁵ and trauma patients are at high risk of delirium during both hospital and ICU stays.³⁶ It seems likely that the impact of ICU stays on mental health may be greater for patients with pre-existing mental health difficulties and may therefore require more prolonged management. These patients may require additional input from other services including psychiatry, psychology, and occupational health to support their onward recovery. Although this prolonged multidisciplinary care would increase LOS, this may contribute to the improved mortality observed in this study, since a multidisciplinary approach to care may improve mortality among critically ill patients.³⁷ The effect of a multidisciplinary approach to trauma is an important area of research and interventional studies are needed to investigate the effect on mortality and functional recovery.

There is a possible biological mechanism for the associations observed in this study. It is increasingly recognized that the immuno-inflammatory response plays an important role in trauma.³⁸ A deranged inflammatory response may result in potentially fatal complications such as multiple organ failure and adult respiratory distress syndrome.³⁹ In depression, there is an increase in proinflammatory cytokines as well as changes

to the hypothalamic–pituitary–adrenal axis.⁴⁰ Indeed, when Weinberg *et al*¹⁴ identified increased postoperative complication rates in orthopedic trauma populations, it was suggested that this may have been the result of an increased acute inflammatory response. However, our finding of reduced mortality in patients with depression does not support this hypothesis and it is possible that more complex differences in the acute inflammatory response may contribute to the outcomes observed in this study. Differences in the inflammatory response to trauma in patients with depression must be assessed in further prospective studies. Such research may have implications for all major trauma patients as identifying possible pathways for immuno-inflammatory modulation and could help produce novel treatment options.

Patients with pre-existing depression in our cohort were more likely to undergo operative intervention. It has been demonstrated in non-trauma populations that low self-efficacy can predict reduced participation in treatment decision making,⁴¹ as well as poorer long-term surgical outcomes.⁴² Considering that depression is associated with low self-efficacy,^{43,44} the increase in operative intervention may be driven by differences in how patients with depression consider and communicate their treatment preferences to clinicians. However, it is not clear from our data whether the differences in operative intervention are due to different patterns of injury, differences in clinicians' propensity to operate, or patients' willingness or capacity to consent to surgery. Nonetheless, in orthopedic trauma, patients with depression are more likely to have postoperative complications¹⁴; therefore, it is important that further investigations are undertaken to explore why these patients underwent surgical intervention more frequently.

The 6% of patients identified in our study cohort with a pre-existing diagnosis of depression is likely to be lower than the true population prevalence.^{2,3} The underidentification of patients with depression in trauma has also been reported by other studies, with one study suggesting that 30.2% of depression diagnoses have been missed during patient assessment.¹⁴ Since the true prevalence of depression was likely underdiagnosed in the current study, there may be some selection bias according to how detailed a history was available during initial presentation. In trauma, a thorough history may prevent missed injuries which would otherwise increase mortality if left undiagnosed.⁴⁵ Additionally, knowledge of previous medications and comorbidities is important for guiding appropriate treatment. It is unknown whether the quality of the clinicians' history might have influenced the results and there is a paucity of literature examining the effect of accurate history taking on trauma mortality. Moreover, although depression is recorded by TARN, it may not be asked about routinely by the treating clinician. Therefore, investigation is needed to identify whether inclusion of depression

Table 5 Association of baseline characteristics with operative intervention in the regression analysis

Baseline characteristics	OR	95% CI	P value
Pre-existing depression	1.36,	1.06 to 1.75	0.016*
CCI	1.02	0.95 to 1.08	0.622
Age	0.98	0.98 to 0.99	<0.001*
Male gender	1.19	1.03 to 1.37	0.020*
ISS	1.04	1.03 to 1.04	<0.001*
GCS score	1.04	1.02 to 1.06	<0.001*

*Indicates statistical significance.

CCI, Charlson Comorbidity Index; GCS, Glasgow Coma Scale; ISS, Injury Severity Score.

as a predefined field within prehospital or ED proformas can enable better identification of these patients and whether this may improve patients' outcomes.

The effect of antidepressant medication on patients' outcomes is currently an area of debate. Whereas some studies suggest that antidepressants may increase surgical complications,⁴⁶ others suggest that this is probably mediated by depression itself rather than the antidepressant medications.⁴⁷ For orthopedic trauma patients, Weinberg *et al*¹⁴ reported that prescribing antidepressant medication to patients with depression did not affect surgical complication rates.¹⁴ However, a further study in orthopedic trauma suggested that delays to prescribing antidepressant medication may mediate increased LOS by inducing withdrawal symptoms and preventing effective engagement with therapy.¹⁵ In major trauma patients, there is little evidence to suggest whether antidepressant medication affects outcomes. Our study did not investigate antidepressant prescription and it is possible that this may have contributed to the outcomes. Further investigations of the effect of antidepressants in major trauma may help identify the optimum pharmacological management of depression.

Limitations

The most significant limitation of our study methodology is the utilization of a database, with risk of omissions in relevant medical history, including depression. However, TARN is known to be a reliable source of data and is commonly used for similar retrospective cohort studies.^{21 48 49} Furthermore, it was not possible to assess the severity of a patient's depression nor how long before the admission they were diagnosed. Additionally, antidepressants may be indicated for other medical conditions and non-pharmacological psychotherapy was not reliably disclosed in clinical records, thus making it impractical to stratify patients based on current treatment. It was therefore not possible to distinguish patients with chronic, well-managed depression from patients with more recent onset, severe or unmanaged depression. Moreover, as previously mentioned, the proportion of patients identified to have depression was lower than expected compared with the UK population. This indicates that some diagnoses of depression are likely to have been missed, which potentially increases the risk of selection bias in this study.

To classify patterns of injury, the mechanisms of injury and AIS scores for each body region were compared between each group. Although there was no significant difference in AIS scores, the groups were not perfectly matched by mechanisms of injury. Although this is an expected limitation of a cohort study design, it is possible that differences in these factors may have influenced the results. Differences in injury patterns may also affect cause of death (such as from hemorrhage or brain injury), but we did not have access to precise causes of death for each patient. The reduced mortality observed in both the current cohort of major trauma patients and two studies of orthopedic trauma populations is conflicting with a study of the general trauma population, but it is unknown what may have caused these differences.^{17 18 20} Additionally, although hospital and ICU admissions have varied over time (figure 2), we did not have access to any changes in precise indications for admission to ICU during the study period. Multicentered prospective studies with greater granularity of data may be warranted to better delineate the relationship between outcomes and different levels of severity of depression and different treatment modalities. We were also unable to measure outcomes once patients left the hospital and therefore could not assess longer-term outcomes.

CONCLUSION

In our database study of 4602 major trauma patients, there was a significant association between a pre-existing diagnosis of depression and survival. Depression was also a significant risk factor for increased hospital and ICU LOS, which may indicate a requirement for additional support with recovery and rehabilitation. There is also an increased incidence of surgical intervention in patients with depression, but it is unclear why. Multicenter prospective investigations should be undertaken to confirm the findings of this study and to identify the underlying mechanisms for these results.
