## Abstract

### Background

The prevalence of risk factors for poor outcomes from aneurysmal subarachnoid hemorrhage (SAH) varies widely and has not been fully elucidated to date in Vietnam. Understanding the risk and prognosis of aneurysmal SAH is important to reduce poor outcomes in Vietnam. The aim of this study, therefore, was to investigate the rate of poor outcome at 90 days of ictus and associated factors from aneurysmal SAH in the country.

### Methods

We performed a multicenter prospective cohort study of patients ( $\geq 18$  years) presenting with aneurysmal SAH to three central hospitals in Hanoi, Vietnam, from August 2019 to August 2020. We collected data on the characteristics, management, and outcomes of patients with aneurysmal SAH and compared these data between good (defined as modified Rankin Scale (mRS) of 0 to 3) and poor (mRS, 4–6) outcomes at 90 days of ictus. We assessed factors associated with poor outcomes using logistic regression analysis.

## Results

Of 168 patients with aneurysmal SAH, 77/168 (45.8%) were men, and the median age was 57 years (IQR: 48–67). Up to 57/168 (33.9%) of these patients had poor outcomes at 90 days of ictus. Most patients underwent sudden-onset and severe headache (87.5%; 147/168) and were transferred from local to participating central hospitals (80.4%, 135/168), over half (57.1%, 92/161) of whom arrived in central hospitals after 24 hours of ictus, and the initial median World Federation of Neurological Surgeons (WFNS) grading score was 2 (IQR: 1–4). Nearly half of the patients (47.0%; 79/168) were treated with endovascular coiling, 37.5% (63/168) were treated with surgical clipping, the remaining patients (15.5%; 26/168) did not receive aneurysm repair, and late rebleeding and delayed cerebral ischemia (DCI) occurred in 6.1% (10/164) and 10.4% (17/163) of patients, respectively. An initial WFNS grade of IV (odds ratio, OR: 15.285; 95% confidence interval, CI: 3.096–75.466) and a grade of V (OR: 162.965; 95% CI: 9.975–2662.318) were independently associated with poor outcomes. Additionally, both endovascular coiling (OR: 0.033; 95% CI: 0.005–0.235) and surgical clipping (OR: 0.046; 95% CI: 0.006–0.370) were inversely and independently associated with poor outcome. Late rebleeding (OR: 97.624; 95% CI: 5.653–1686.010) and DCI (OR: 15.209; 95% CI: 2.321–99.673) were also independently associated with poor outcome.

## Conclusions

Improvements are needed in the management of aneurysmal SAH in Vietnam, such as increasing the number of aneurysm repairs, performing earlier aneurysm treatment by surgical clipping or endovascular coiling, and improving both aneurysm repairs and neurocritical care.

## Introduction

Subarachnoid hemorrhage (SAH) is often a devastating event with high mortality, morbidity, and burden of healthcare [1, 2]. The mortality rate is approximately 50% in population-based studies with a trend towards gradual improvement [3–5]. This mortality rate includes 10–18% of all patients with aneurysmal SAH who die at home or during transportation to the hospital [6, 7]. Among patients who reach the hospital alive, subsequent early death is caused by the common complications of aneurysmal SAH related to initial bleeding, rebleeding, delayed cerebral ischemia (DCI), hydrocephalus, increased intracranial pressure (ICP), seizures, and cardiac complications [8–10]. Additionally, patients with aneurysmal SAH who are discharged alive from the hospital have an increased long-term mortality rate compared with the general population [11–15]. Patients who are discharged alive from the hospital also have high rates of memory and neurocognitive impairment [16, 17]. At three months after aneurysmal clipping, global impairment was present in approximately 20% of all patients who were discharged alive from the hospital and in 16% of those with excellent preoperative conditions [18]. The location of the aneurysm responsible for aneurysmal SAH does not appear to influence the cognitive outcome compared to the occurrence of DCI and other complications [15, 19, 20].

Advances in diagnostic and treatment strategies for aneurysmal SAH, through the introduction of computed tomography (CT) angiography with early detection of aneurysms, the

use of nimodipine, specialist care for patients, and endovascular coiling of ruptured aneurysms, have substantially improved the outcomes of hospitalized patients [21–24]. Despite these improvements, aneurysmal SAH continues to exact a high economic and social cost [25]. It remains a disease of relatively young people and causes a loss of productive life-years similar to that of ischemic stroke.

Economic and political reforms have spurred rapid economic growth in Vietnam [26]. However, medical providers still have difficulty caring for patients with aneurysmal SAH in local settings because of low resources and a lack of advanced diagnostic and treatment strategies [27, 28]. Furthermore, although national health insurance was established in 1992 to improve access to health care and mitigate the negative impact of user fees introduced in 1989, advances in diagnosis and treatment are incompletely covered by health insurance. At the same time, the medical staff may not be sufficiently well trained or experienced to be able to recognize aneurysmal SAH and other severe conditions in their patients and provide the required care [27–29]. Additionally, within the healthcare system in Vietnam, central hospitals are responsible for receiving patients who have difficulty being treated in local hospital settings [30]. Therefore, the initiation of aneurysm treatment and appropriate supportive care in patients with aneurysmal SAH is often delayed [27, 28].

Understanding the country-specific causes, risks, and prognosis of aneurysmal SAH is important to reduce poor outcomes and mortality in Vietnam. The aim of this study, therefore, was to investigate the rate of poor outcomes and associated factors from aneurysmal SAH in the country.

## Methods

### Study design and setting

We performed a multicenter prospective observational cohort study that included all patients with aneurysmal SAH consecutively admitted to the emergency departments (EDs) of the three national tertiary hospitals (Vietnam-Germany Friendship, Bach Mai, and Hanoi Medical University Hospital) in Hanoi, Vietnam, between August 2019 and August 2020. These hospitals were designated central hospitals (level I) in northern Vietnam by the Ministry of Health (MOH) of Vietnam [29, 30], of which the first is a surgical hospital with 1,500 beds, the second is a larger general hospital with 3,200 beds, and the last is a smaller general hospital with 580 beds. In the healthcare system of Vietnam, central hospitals are responsible for training hospital staff and treating patients who are unable to be adequately treated in local hospital settings, including provincial and district hospitals (levels II and III, according to the MOH of Vietnam).

### Participants and treatments

This study included all patients (aged 18 years or older) presenting with aneurysmal SAH to the EDs of the three central hospitals within 4 days of ictus. We defined a case of aneurysmal SAH as a person who had the presence of blood on head CT scan (or in case CT scan was negative on the presence of xanthochromia in cerebral spinal fluid) in combination with an aneurysm confirmed on CT or digital subtraction angiography (DSA) [16]. We excluded patients for whom the Glasgow coma scale (GCS) on admission was unable to score (e.g., the patients intubated before arrival in the central hospital) or neurological functional outcome was unknown at 90 days of ictus.

All patients were managed following the American Heart Association (AHA)/American Stroke Association (ASA) guidelines for the management of aneurysmal SAH [16]. Aneurysm repair with surgical clipping or endovascular coiling was performed as early as possible and

immediately if rebleeding did occur. The decision to treat cerebral aneurysms was at the discretion of the physician in charge of the patients and the availability of neurosurgical clipping or endovascular coiling, which depended on the participating hospital or the financial situation (either insurance or patient self-pay).

## Data collection

The data for each study patient were recorded from the same unified samples (case record form). A case record form was adopted across the study sites to collect common variables. Data were entered into the study database by EpiData Entry software, which was used for simple or programmed data entry and data documentation that could prevent data entry errors or mistakes. Patient identifiers were not entered in the database to protect patients' confidentiality.

## Variables

We included variables based on unruptured intracranial aneurysm (UIA) and SAH work group (WG) recommendations [31], such as information on:

- Assessments and examinations, including histories (e.g., stroke, UIA, etc.); clinical presentation (e.g., GCS and focal neurological signs); SAH grading scales such as the WFNS grading scale ranging from grade I (GCS score of 15) to V (GCS scores of 3 to 6) of which focal deficits making up 1 additional grade for patients with a GCS score of 14 or 13 [32] and the Hunt and Hess scale also consists of five grades ranging from minimally symptomatic to coma [33].
- Laboratory, such as coagulation tests (e.g., platelets, prothrombin time and international normalized ratio) and other tests.
- Neuroimaging, such as admission CT scan (e.g., presence of SAH, IVH or ICH, and Fisher scale) and follow-up CT scan during hospitalization (e.g., presence of SAH, IVH or ICH) or at 30 and 90 days of ictus (e.g., presence of chronic hydrocephalus).
- Management, including surgical and endovascular interventions (i.e., surgical clipping or endovascular coiling); rescue therapies (e.g., surgical hematoma evacuation, decompressive craniectomy, EVD placement, VP shunt); and intensive care unit (ICU) therapies (e.g., mechanical ventilation).
- Neurological complications, including early and late rebleeding, which included bleeding into the subarachnoid space, intracerebral, intraventricular, or subdural compartments and catheter-induced hemorrhages; DCI; acute hydrocephalus, which was defined as marked symmetrical dilatation of the ventricles with an Evans ratio of at least 0.3 on admission [34].
- Hospital course and outcomes, including length of hospitalization, discharge status (e.g., hospital discharge, transfer to another hospital, "discharged to die" decision in which almost all patients were in grave condition or dying and classified with a modified Rankin Scale (mRS) score of 5 (severe disability) at the time of discharge [35], and death in hospital); functional outcomes at 30 and 90 days of ictus, such as mRS scores ranging from 0 (no disability) to 6 (death) [36]; and death at 30 and 90 days of ictus.

We also collected data on behavioral history (e.g., cigarette smoking, alcohol drinking), demographics (i.e., sex, age), and social status (e.g., health insurance, occupations, highest education levels, annual income).

## Outcomes

The primary outcome of the study was poor neurological function (poor outcome) at 90 days of ictus, which was defined as mRS scores of 4 (moderately severe disability) to 6 (death) [35, 37]. We also examined the following secondary outcomes: poor outcome at 30 days of ictus, mortality rate at 30 and 90 days of ictus, and incidence of complications.

## Data analyses

We used IBM<sup>®</sup> SPSS<sup>®</sup> Statistics 22.0 (IBM Corp., Armonk, United States of America) for data analysis. We report data as numbers and percentages for categorical variables and medians and interquartile ranges (IQRs) or means and standard deviations (SDs) for continuous variables. Comparisons were made among methods of aneurysm repair, between poor and good outcomes, and between alive and dead patients for each variable using the  $\chi^2$  test or Fisher exact test for categorical variables and the Mann–Whitney U test, Kruskal–Wallis test, one-way analysis of variance for continuous variables. We assessed factors associated with poor outcome or death using logistic regression analysis and included independent variables related to the patient (age, sex, risk factors for aneurysmal SAH, comorbidities), the SAH event (onset symptoms, presentation on admission, and SAH severity), therapy provided (e.g., no aneurysm repair, endovascular coiling, and surgical clipping) and complications (e.g., DCI) if the P-value was  $< 0.05$  in the bivariate analysis between poor and good outcomes and between alive and dead patients. We used a stepwise method to select variables and then used the backward method with these variables. We present odds ratios (ORs) and 95% confidence intervals (CIs). For all analyses, significance levels were two-tailed, and we considered  $P < 0.05$  to be statistically significant.

## Ethical issues

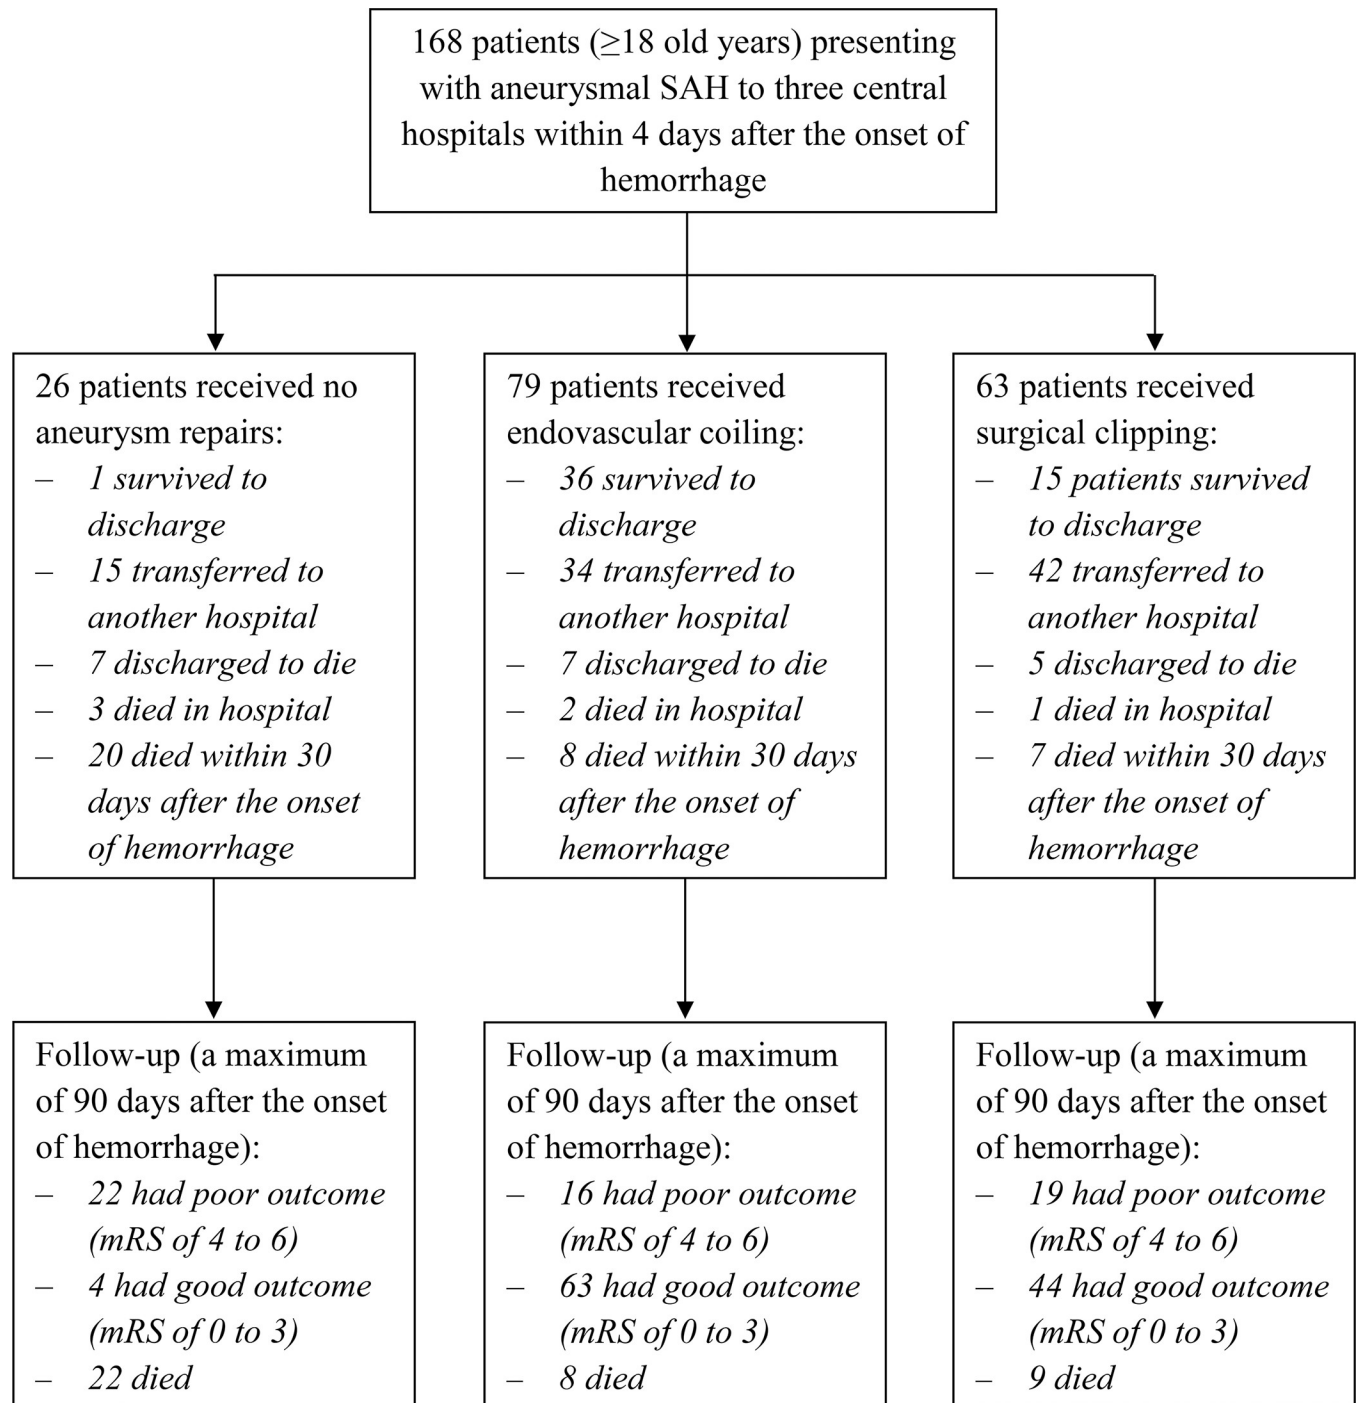

The Hanoi Medical University (Approval number: 3335/QĐ-ĐHYHN), Vietnam-Germany Friendship Hospital (Approval number: 818/QĐ-VĐ; Research code: KH04.2020), and Bach Mai Hospital (Approval number: 3288/QĐ-BM; Research code: BM\_2020\_1247) Scientific and Ethics Committees approved this study. The study was conducted according to the principles of the Declaration of Helsinki. The Vietnam-Germany Friendship Hospital Scientific and Ethics Committees waived written informed consent for this noninterventional study, and public notification of the study was made by public posting. The authors who performed the data analysis kept the data sets in password-protected systems, and we present anonymized data.

## Results

### General characteristics, treatment, and outcomes

During the observation period, a total of 168 patients presented to the study sites with aneurysmal SAH (Fig 1). Among these patients, 33.9% (57/168) of patients had a poor outcome, and 23.2% (39/168) died at 90 days of ictus. In addition, intracerebral (ICH) and intraventricular hemorrhages (IVH) were also detected on the admission CT scan in 24.4% (41/168) and 63.7% (107/168) of patients, respectively. Of the 168 patients with aneurysm SAH, 10/164 (6.1%) had late rebleeding of aneurysmal SAH, and DCI occurred in 17/163 (10.4%) patients. The characteristics, complications, clinical time course, and outcomes of patients were compared between methods of aneurysm treatment, as shown in Table 1.

The median age of patients who had a good outcome (56 years; IQR: 46–65) was younger than that of patients who had a poor outcome (63 years; IQR: 53.5–71.5;  $p < 0.001$ ). There was

**Fig 1. Flowchart of aneurysm treatment and outcome of patients with aneurysmal subarachnoid hemorrhage included in the study (mRS, modified Rankin Scale; SAH, subarachnoid hemorrhage).**

<https://doi.org/10.1371/journal.pone.0256150.g001>

a significant difference ( $p < 0.001$ ) between patients who had a good outcome and patients who had a poor outcome according to the severity of aneurysmal SAH (e.g., WFNS grading scale, Fisher scale, etc.). In addition, ICH (19.8% [22/111] vs. 33.3% [19/57],  $p = 0.054$ ) and IVH (55.0% [61/111] vs. 80.7% [46/57],  $p = 0.001$ ) were less commonly detected on the admission

<https://doi.org/10.1371/journal.pone.0256150.t001>

CT scan of patients who had good outcomes than those of patients who had poor outcomes. Although no difference was observed in surgical clipping between patients who had good outcomes (39.6%; 44/111) and patients who had poor outcomes (33.3%; 19/57;  $p = 0.424$ ), there

was a higher rate of endovascular coiling in patients who had good outcomes (56.8%; 63/111) than in patients who had poor outcomes (28.1%; 16/57;  $p < 0.001$ ). Both late rebleeding of aneurysmal SAH (0.9% [1/110] vs. 16.7% [9/54],  $p < 0.001$ ) and DCI (4.6% [5/108] vs. 21.8% [12/55],  $p = 0.001$ ) were less common in patients who had good outcomes than in patients who had poor outcomes. The characteristics, treatment, and outcomes of patients were compared between patients who had a good outcome and patients who had a poor outcome, as shown in [Table 2](#).

### Factors associated with poor outcome and mortality

Several factors were independently associated with poor outcome on patients with aneurysm SAH at both 30 and 90 days of ictus, including blood filling the basal cistern (OR: 3.736, 95% CI: 1.082–12.899 and OR: 4.062, 95% CI: 1.102–14.981, respectively); admission WFNS grade of IV (OR: 14.367, 95% CI: 3.155–65.429 and OR: 15.285, 95% CI: 3.096–75.466, respectively) and grade of V (OR: 54.391, 95% CI: 4.831–612.362 and OR: 162.965, 95% CI: 9.975–2662.318, respectively); endovascular coiling (OR: 0.032, 95% CI: 0.005–0.194 and OR: 0.033, 95% CI: 0.005–0.235, respectively); surgical clipping (OR: 0.044, 95% CI: 0.007–0.291 and OR: 0.046, 95% CI: 0.006–0.370, respectively); late rebleeding (OR: 71.142, 95% CI: 4.915–1029.672 and OR: 97.624, 95% CI: 5.653–1686.010, respectively); and DCI (OR: 11.581, 95% CI: 1.897–70.698 and OR: 15.209, 95% CI: 2.321–99.673, respectively). Further analysis also showed that late rebleeding (OR: 10.153, 95% CI: 1.557–66.219 and OR: 22.588, 95% CI: 3.619–141.000) was independently associated with mortality at both 30 and 90 days of ictus. Factors associated with poor outcome and mortality are shown in [Table 3](#).

### Discussion

In this study, most of the patients with aneurysmal SAH (80.4%) were transferred from local hospitals to participating hospitals ([Table 1](#)). Participating hospitals are the central hospital in northern Vietnam and are responsible for treating patients with severe conditions from lower-level hospitals as well as educating and training medical providers at local hospitals [30]. This is one of the main reasons for the present study, namely, to examine the outcome of patients transferred from local hospitals.

Our study shows that poor outcomes at 30 and 90 days of ictus were observed in over a third (34.5% and 33.9%, respectively) of patients with aneurysmal SAH; death at 30 and 90 days of ictus was observed in over a fifth (20.8% and 23.2%, respectively) of patients ([Table 1](#)). The mortality rates of our patients at 30 and 90 days of ictus were lower than the rates reported in previous studies (22–25% and 25–29%, respectively) [5, 38]. These differences might be because our cohort is likely to be selected, as many patients with aneurysmal SAH in Vietnam are not transferred to the central hospital and might die in the local hospital, as well as die outside of the hospital [39], and might also be attributed to our study only including patients presenting to the participating hospitals within 4 days of ictus and excluding patients for whom admission GCS was unable to score (e.g., in the intubated patients). Therefore, our cohort may not reflect all aneurysmal SAHs in the region.

In our study, the proportions of ICH and IVH detected on admission CT scan were higher than the rates reported in a previous study (20.9%, 1120/5362; 49.7%, 2628/5362, respectively) [40]. While most rebleeding occurs in the subarachnoid space, bleeding can also occur in the intraparenchymal, intraventricular, or subdural compartments. After aneurysmal SAH, the risk of early rebleeding is 4 to 14% in the first 24 hours [1, 16]. Our study shows that over half of patients arrived in participating hospitals after 24 hours of ictus, and nearly half of patients who did not receive aneurysm repair took over 24 hours from ictus to participating hospital

arrival (Table 1). Therefore, these differences in terms of ICH and IVH rates might be attributed to early rebleeding in our study. Additionally, a unique characteristic of patients with aneurysmal SAH or other clinical conditions in Vietnam is that many of these patients are diagnosed with SAH in local hospitals and are then transferred to a central hospital if their conditions become severe [30]. This leads to delayed diagnosis and delayed initiation of aneurysm repair for aneurysmal SAH, which can, in turn, lead to high complications, poor outcomes, and mortality rates [27, 28, 41]. Thus, to reduce poor outcomes and mortality, improvements are needed in human, medical, and sociological resources at local levels.

In our study, the proportion of patients with aneurysmal SAH who had a WFNS grade of III or more was 44% (74/168), which was higher than the rate reported in a previous study (35.6%; 1910/5362) [40], of which most patients (92.3%; 24/26) who did not receive aneurysm repair had a WFNS grade of III or more (S1 Table in S1 File). In previous studies, several factors were identified as predictors of rebleeding, including longer time to aneurysm treatment and worse neurologic status on admission [16, 42–46]. Additionally, aneurysm treatment is the only effective treatment for the prevention of rebleeding [16]. Therefore, our patients with aneurysmal SAH should have emergency aneurysm repair. In addition to the high risk of early rebleeding after aneurysmal SAH, patients with aneurysmal SAH remain at an elevated risk of rebleeding for 30 days after the initial rupture if the aneurysm is not treated [1, 16]. In our study, a substantial number of patients who did not receive aneurysm repair had a poor WFNS grade on admission and consequently received “discharged to die” decisions (Table 1). In a literature review, the mortality associated with rebleeding was reported to be as high as 70% [47]. However, our study shows that both surgical clipping and endovascular coiling were inversely and independently associated with poor outcomes at both 30 and 90 days of ictus (Table 3). Thus, to reduce the poor outcome and mortality, increasing the number of aneurysm repairs and performing earlier aneurysm treatment with surgical clipping or endovascular coiling are needed.

Our study also shows that the rates of acute hydrocephalus, late rebleeding, DCI, and nosocomial pneumonia were significantly more often observed in patients who had poor outcomes than in patients who had good outcomes (Table 2). However, only late rebleeding and DCI were independently associated with poor outcomes at both 30 and 90 days of ictus (Table 3). Previous studies have also shown that DCI is a frequent complication of SAH; it contributes substantially to morbidity and mortality after SAH [19, 48]. However, the risk of late rebleeding is low but is more common after endovascular coiling (2.9%) than after surgical clipping (0.9%) [24]. Therefore, improvements are needed in both aneurysm treatments and neurocritical care.

Our study has some limitations. Our data are from a selected population of cases that were transferred to the three highest-level public sector hospitals in Vietnam. Therefore, the number of patients with aneurysmal SAH is likely to be considerably higher. Additionally, data were

missing for some variables, e.g., in only 83 patients were the data recorded if chronic hydrocephalus was given or not. Moreover, this study only included patients presenting to the participating hospitals within 4 days of ictus and excluded patients for whom admission GCS was unable to score (e.g., the patients intubated before arrival in the central hospital). These factors resulted in incomplete enrollment of patients in the database of the study, which may have introduced selection bias [49]. These limitations might account for some differences in figures reported from other countries.

## Conclusions

This study investigated selected cohort of patients with aneurysmal SAH presenting to central hospitals. Patients with aneurysmal SAH were transferred from local to central hospitals in northern Vietnam with high poor outcomes and mortality rates. At 30 and 90 days of ictus, admission WFNS grades of IV and V and late rebleeding were independently associated with poor outcomes and deaths, and endovascular coiling and surgical clipping were inversely and independently associated with poor outcomes and deaths. DCI was also independently

associated with poor outcomes at both 30 and 90 days of ictus. To reduce the poor outcome and mortality in patients with aneurysmal SAH, the management of aneurysmal SAH in Vietnam needs to be enhanced through, for example, increasing the number of aneurysm repairs, performing earlier aneurysm treatment by surgical clipping or endovascular coiling, and improving both aneurysm repairs and neurocritical care.

## Acknowledgments

We thank all staff of the Center for Emergency Medicine, the Department of Neurosurgery, and the Radiology Center at Bach Mai Hospital for their support with this study. We thank all staff of the Neurosurgery Center at Vietnam-Germany Friendship Hospital for their support with this study, as well as the Emergency and Critical Care Department at Hanoi Medical University Hospital. We also thank the staff of the Faculty of Public Health at Thai Binh University of Medicine and Pharmacy for their support and statistical advice. Finally, we thank the staff of American Journal Experts for their support with the final version of our manuscript.

## Author Contributions

**Conceptualization:** Chinh Quoc Luong, Hung Manh Ngo, Hai Bui Hoang.

**Data curation:** Chinh Quoc Luong, Hung Manh Ngo, Hai Bui Hoang, Tuan Anh Nguyen, Tuan Anh Tran, Duong Ngoc Nguyen, Hung Dinh Vu, Hien Thi Thu Vuong, Linh Quoc Nguyen, Trang Quynh Pham.

**Formal analysis:** Chinh Quoc Luong, Dung Thi Pham, My Ha Nguyen.

**Investigation:** Chinh Quoc Luong, Hung Manh Ngo, Hai Bui Hoang, Dung Thi Pham, Tuan Anh Nguyen, Tuan Anh Tran, Duong Ngoc Nguyen, Son Ngoc Do, My Ha Nguyen, Hung Dinh Vu, Hien Thi Thu Vuong, Ton Duy Mai, Anh Quang Nguyen, Kien Hoang Le, Phuong Viet Dao, Thong Huu Tran, Luu Dang Vu, Linh Quoc Nguyen, Trang Quynh Pham, He Van Dong, Hao The Nguyen, Chi Van Nguyen, Anh Dat Nguyen.
