Traumatic insemination (TI) is a rare reproductive behaviour characterized by the transfer of sperm to the female via puncture wounds inflicted across her body wall. Here, we challenge the claim made by Kamimura (Kamimura 2007 *Biol. Lett.* **3**, 401–404. (doi:10.1098/rsbl.2007.0192)) that males of species of the *Drosophila bipectinata* complex use a pair of claw-like processes (claws) to traumatically inseminate females: the claws are purported to puncture the female body wall and genital tract, and to inject sperm through the wounds into the lumen of her genital tract, bypassing the vaginal opening. This supposed case of TI is widely cited and featured in prominent subject reviews. We examined high-resolution scanning electron micrographs of the claws and failed to discover any obvious ‘groove’ for sperm transport. We demonstrated that sperm occurred in the female reproductive tract as a single-integrated unit, inconsistent with the claim that sperm are injected via paired processes. Laser ablation of the sharp terminal ends of the claws failed to inhibit insemination. We showed that the aedeagus in the complex delivers sperm through the vaginal opening, as in other *Drosophila*. The results refute the claim of TI in the *Drosophila bipectinata* species complex.

1. Introduction

Traumatic insemination (TI) is a form of mating behaviour during which males deploy specialized ‘devices’, such as spines and stylets, to puncture the female body wall and transfer sperm through the wound(s) they inflict [1]. This extraordinary behaviour is distinguished from other forms of ‘traumatic mating’, where only non-sperm components of the ejaculate, or no ejaculate at all, transfer to the female through the male-inflicted wounds [1–4]. Though rare, TI has arisen independently in a number of animal groups [3,5], and the evolutionary drivers of this unusual form of insemination are the focus of ongoing debate [1,5–9].

It has been claimed by Kamimura [10] that TI occurs in species of the *Drosophila bipectinata* complex, a small taxonomic grouping of four very similar species within the *ananassae* subgroup, of the *melanogaster* species group, that includes: *Drosophila bipectinata* Duda, 1923; *Drosophila parabiptectinata* Bock, 1971; *Drosophila malerkotliana* Parshad and Paika, 1965; and *Drosophila pseudoananassae* Bock, 1971 [11]. Specifically, males of this complex are purported by Kamimura to use a pair of claw-like phallic structures to pierce both the female body wall and reproductive tract, and to inject sperm into the lumen of her reproductive tract through the wounds. If true, then TI in the complex would be an astonishing evolutionary innovation within the genus, family and order.

In *Drosophila*, the ‘typical’ route of sperm transfer, storage and use is well documented in *Drosophila melanogaster* [12]: the ejaculate, comprising sperm

and seminal plasma, passes via the tip of the aedeagus into the female bursa (uterus) through her gonopore (vaginal opening) [13–16]. The ejaculate, immediately after transfer to the female, exists in this and other species as a single sperm mass readily visualized by teasing open her reproductive tract and releasing it [15,17,18].

In Kamimura's study, a laser scan micrograph showing two areas of coloration adjacent to the tips of the basal processes was claimed to demonstrate TI (Fig. 1c(ii) in [10]); the following is the relevant excerpt: 'TI clearly occurs in the *bipectinata* complex, as the basal processes pierce the pockets during copulation and sperm is ejaculated through the wounds but not through the genital orifice...' [10]. We were sceptical about this conclusion, as no evidence for the passage of sperm via such a route was actually provided. The following statement likewise gave us pause, as no direct evidence for it was presented either: 'The basal processes of this group have a groove on the dorsal surface which may transport semen' [10, p. 404].

Here, we challenge the claim that TI occurs in the *bipectinata* complex. Our results provide observational and direct experimental evidence contradicting it: the evidence supports sperm transfer occurring via the route described for other *Drosophila*, that is, from the aedeagus into the reproductive tract via the female gonopore. Recently, Rice *et al.* [19] showed that the claws have a distinct developmental origin, deriving from the lateral portions of the central primordium of the phallus observable during pupal metamorphosis. Since most cells of the central primordium normally give rise to the aedeagus, the term *aedeagal lateral processes* for the claw-like structures was proposed [19], a term we adopt here and use interchangeably with 'claws'. Historically, the claws were thought to be arms of a bifid aedeagus [11,20–23] and were termed 'basal processes' by Kamimura [10].

We examined scanning electron micrographs (SEMs) of the claws at varying orientations and magnifications to search for a possible conduit for sperm—namely, Kamimura's purported 'groove'. We then addressed two additional predictions. If insemination occurs traumatically via the paired claws, we would expect the sperm mass to occur as two discernible units within the female reproductive tract immediately after and/or during mating. To this end, we examined the sperm masses extracted from the female reproductive tract both immediately after the terminus of uninterrupted, full length (*ca* 10.5 min) copulations, and after pairs were interrupted 6–8 min after the onset of coupling, that is, during sperm transfer. Reproductive structures of both sexes were also examined after interrupted copulation, which led us to image the functional aedeagus and to identify the path of sperm passage to the female. As a final test, we used laser surgical ablation [24] to eliminate the pointed tips of the claws. If, as claimed by Kamimura, the claws serve to pierce the female's body wall and to transfer sperm to her reproductive tract, males with surgically ablated piercing devices should fail to transfer sperm.

2. Material and methods

(a) Source and culturing of flies

Drosophila bipectinata, *D. parabipectinata* and *D. malerkotliana* cultures were established with field-caught flies; collection and culture methods are provided in the electronic supplementary material. Specimens from these cultures, used for morphological

examination and imaging, are vouchered in the Australian Museum (K.380306, -07, -27).

(b) Laser surgery

Laser surgical ablation is described in the electronic supplementary material. Pulses of laser light were used to ablate one-quarter to one-third of both claws of individual males—the 'cut' group. After surgery, males recovered in groups of 3–5 in food vials for at least 4 days until being paired with virgin females. 'Uncut' control males were treated identically, except that instead of cutting the claws, 2–4 large setae near the end of the abdomen were ablated [24].

(c) Mating trials and dissections

Cut and uncut males were individually paired with a virgin female in 46 mating trials (detailed in the electronic supplementary material): the mating pairs in 42 trials (34 *D. bipectinata*, 8 *D. parabipectinata*) involved cut males, and males in four trials (2 *D. bipectinata*, 2 *D. parabipectinata*) were uncut controls. Immediately after decoupling, females were dissected and the sperm mass released into physiological saline to determine whether it occurred as a single unit or more than one unit. In separate trials ($n = 12$), copulation was interrupted 6–8 min after starting; immediately upon interruption, the female reproductive tract was dissected to visualize the sperm mass.

(d) Imaging phallic structures

Genitalia were dissected from fresh and alcohol-preserved specimens and imaged using light and scanning electron microscopy (detailed in the electronic supplementary material). Membrane-clearing KOH was used for preparing the specimens in figure 1*a–e*, but not figure 1*f–i*. To search for possible sperm conduits along the claws, multiple SEMs were taken at different magnifications (350–3500 \times) and orientations. Genitalic preparations of 28 *D. parabipectinata*, 29 *D. bipectinata* and 3 *D. malerkotliana* were imaged using electron microscopy; a total of 166 SEMs of claws were examined and archived.

3. Results

(a) Phallic architecture of the *bipectinata* species complex

The phallic structures of all four species in the *bipectinata* complex are similar [13]; here, we describe the phallic architecture of *D. bipectinata* and *D. parabipectinata* as representing the complex. The aedeagal lateral processes (claws) are large, curved, apically pointed and bare (figures 1*c,d* and 2*a–e*), approximately 100 μm in length from base to tip, and they articulate with the apex of the phallopodeme (arrowed in figure 1*d*). The claws are bilaterally symmetrical and arise from the lateral portions (shoulders) (figure 1*a,d,e*), not the centre, of the phallopodeme apically. The membranous aedeagus arises centrally between the claws (figure 1*f,g*), but is not apparent after processing with KOH (figure 1*a,d*).

We see no connection between the base of the pregonites and the claws (figure 1*d,e*), which confirms that the claws are not 'basal extensions' of the pregonites evident in allied species of the *D. ananassae* complex [21,25]. The postgonal sheath (*sensu* [19]) folds and bends freely, and is bilaterally symmetrical, lobe-like and 'cloaks' the claws dorsally (figure 2*a–d*). When viewed via light microscopy, the postgonal sheath is largely membranous and translucent (figure 1*c*), with hardened

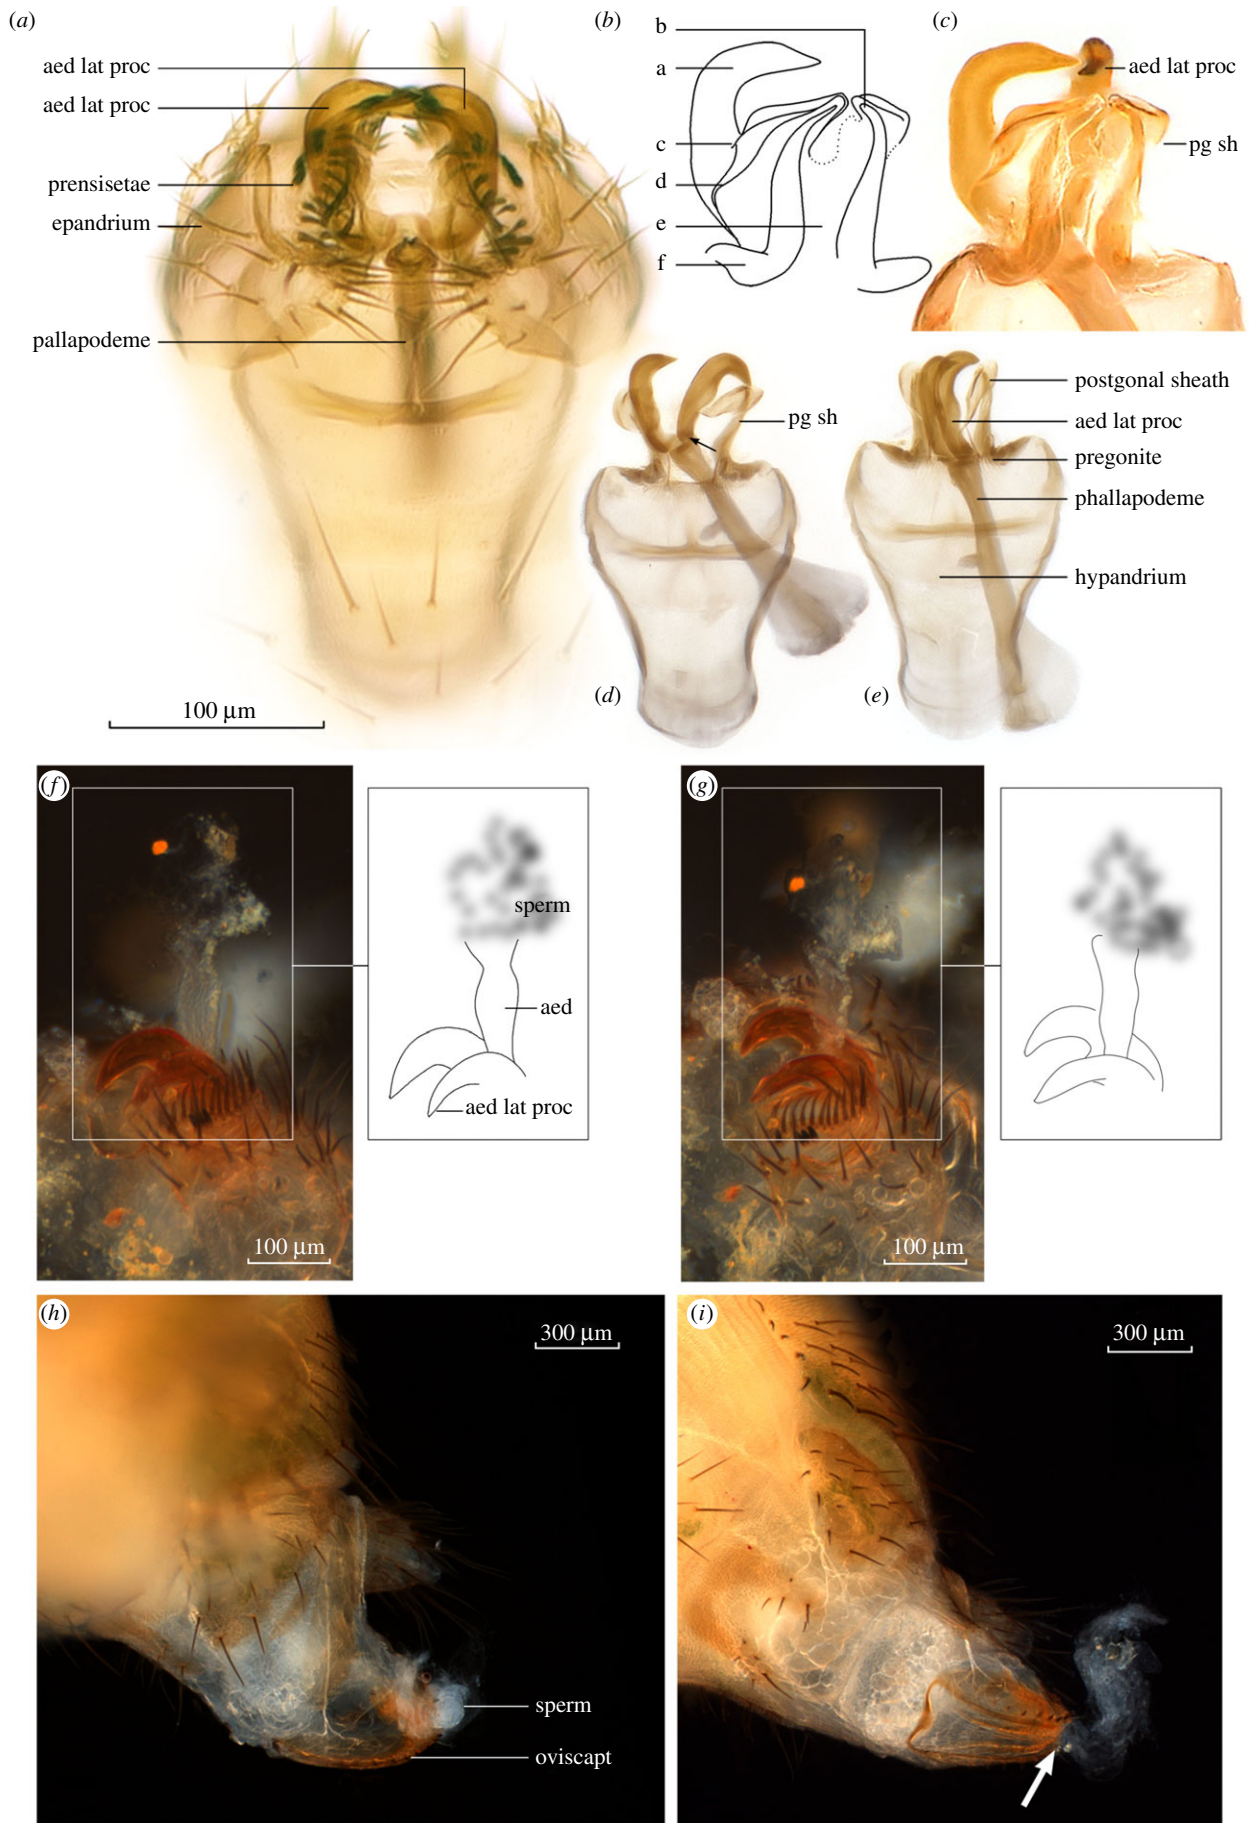

Figure 1. Light microscope images of reproductive structures of the *bipectinata* complex. (a) Hyandrium inside male body. (b,c) Drawing and digital image of posterior end of hyandrium, showing the aedeagal lateral processes (a, aed lat proc, claws) and the postgonal sheath (e, pg sh). Ridges and thickened processes (b, c, d, f) of the sheath are evident. (d,e) Aedeagal lateral processes and postgonal sheath in two phallapodeme orientations; articulation of the aedeagal lateral process with phallapodeme arrowed in (d). (f,g) Extruded aedeagus of a male *D. bipectinata*, arising from between the bases of the claws, showing sperm emanating from its tip. (h,i) Sperm seeping from the female gonopore (sperm teased further out arrowed in (i)).

Figure 2. SEMs of the aedeagal lateral processes (aed lat proc) of the *bipectinata* complex. (a) Ventral surface of hypandrium with the pair of aedeagal lateral processes, cloaked in the postgonal sheath (pg sh). (b,c) Smooth, seamless ventral surfaces of the claws. Pregonite (pregt) with apical sensilla. (d) Ventral and lateral surfaces of the aedeagal lateral processes. Dehydration during scanning electron microscopy preparation likely accounts for the shallow medial depressions in (c) and (d). (e) Dorsal surface of an aedeagal lateral process with depression at its tip, possibly an abrasion. (f) Reticulated mat of tissue between the bases of the claws, likely to be the collapsed aedeagus. (g,h) Examples of the aedeagal lateral processes experimentally blunted (arrowed) using a surgical laser. Both tip-ablated processes visible in (h).

outer ridges and leaf-like structure connected near the base of each claw (figure 1b–e).

(b) The traumatic insemination hypothesis

We could identify no channel, groove or fold, medially, laterally, dorsally or ventrally on the claws that could function as a conduit for sperm (figure 2). In some preparations, we observed the tip of one or both claws to have an irregular depression or lesion (typically $\leq 1 \mu\text{m}$ in diameter), which could, owing to the irregular (torn) edges, be the result of abrasion (figure 2e).

When females were dissected at copulation termination, the sperm within the bursa invariably occurred as a single mass (electronic supplementary material, figure S1A). Out of a total of 12 matings interrupted at 6–8 min after the start of mating, 11 also invariably produced a single sperm mass within the female reproductive tract (electronic supplementary material, figure S1B). In three of these 11 cases, the sperm mass was small and appeared irregular in shape, amorphous, not smoothly oval or rounded, but nevertheless unquestionably as a single undifferentiated unit. In one interrupted mating, there was no ejaculate transfer at all.

The aedeagus was discovered when anaesthetized copulating pairs were gently pulled apart while submerged in saline solution. This organ in *D. bipunctinata* is translucent, membranous and pliable, and it appears to have a textured (scaly) surface (figure 1f). Sperm were readily identified emanating from its tip (figure 1f,g) and could be gently drawn further out using a minuten pin. The aedeagus arises from between the bases of the aedeagal lateral processes (figure 1f,g)—in our SEMs, a reticulated mat of tissue between the bases of the claws could be discerned (figure 2f), which we interpret to be the collapsed aedeagus. In the female of the separated pair, sperm was observed seeping from the gonopore (the orifice of her reproductive tract through which eggs also exit) (figure 1h), and likewise, could be drawn further out of the gonopore (arrowed figure 1i).

Of the 30 total copulations achieved by cut males (figure 2g,h), 22 (73%) resulted in sperm transfer to the bursa as a single mass (electronic supplementary material, table S1 and figure S1C,D). Among the eight cut males that copulated but failed to transfer sperm to the female bursa, two remained fastened to the female in an end-to-end position after dismounting. In one case, ejaculate seeped out from between the pair and remained attached to the male's terminalia after the pair separated (electronic supplementary material, figure S2). This viscous, whitish mass contained sperm, indicating that it was leaked ejaculate, and that sexual union was incomplete.

4. Discussion

In their authoritative review of copulatory wounding, Lange *et al.* [1] listed a set of criteria for establishing the existence of traumatic mating in a given species. Here, building upon this work and that of Tataric *et al.* [5], we suggest that evidence for TI should minimally include (i) a specific wounding structure(s) that demonstrably breaches the female body wall; (ii) physical features of said structure(s), such as a canal, lumen, groove and/or pore, for the transfer and delivery of spermatozoa; and (iii) the transfer of spermatozoa across the female body wall. Several studies have demonstrated TI by fulfilling

these criteria (e.g. [9,26–28]), a textbook example of which occurs in bed bugs (Cimicidae) ([26,27,29]; and see electronic supplementary material, figure S3).

By contrast, we contend that none of these criteria was convincingly met by Kamimura [10]. In the first place, whereas Kamimura claimed that integumental piercing is achieved by the claws, there was no direct evidence presented for physical penetration of the female body wall (nor the genital tract for that matter). The second criterion (the functional morphology of the organ) was not fulfilled either, as convincing visual evidence for a structure that could guide and transfer sperm across the female body wall was also not provided, and according to the present investigation, does not exist (and see below). Finally, although Kamimura claimed that 'sperm is ejaculated through the wounds but not through the genital orifice' [10, p. 404], the evidence he presented—areas of pink coloration in laser scan micrographs—we regard as unconvincing since the presence of sperm within the pink 'clouds' was not confirmed, let alone sperm transfer via the claws to the reproductive tract.

Our results refute the hypothesis of TI in the *bipunctinata* species complex, and therefore in *Drosophila*, and for that matter in Diptera as far as we know. Sperm transfer in the *bipunctinata* complex occurs as in *D. melanogaster*, from the male aedeagus into the female reproductive tract via her gonopore. We examined SEMs of the dorsal, lateral and ventral surfaces of the claws in *D. parabipectinata*, *D. bipunctinata* and *D. malerkotliana* and could identify no obvious 'groove' for sperm transport. We next tested the prediction that immediately after and/or during mating, the ejaculatory mass within the female should be discernible as two units. The prediction failed, as sperm invariably occurred as a single mass, comporting with previous work [30]. We also tested the experimental prediction that after surgically eliminating the sharp terminal ends of the claws, insemination would be inhibited. This prediction also failed, as a majority of males (73%) without these sharp ends successfully inseminated females, and in all these cases, the sperm occurred as a single mass within the female reproductive tract.

Another decisive blow to the TI hypothesis is that we unambiguously imaged the functional aedeagus in the *D. bipunctinata* complex. Pulling apart mating pairs of *D. bipunctinata* clearly revealed sperm releasing simultaneously from the tip of a hitherto unknown aedeagus and the counterpart female gonopore, thus identifying the route of gamete transfer between the sexes. The aedeagus is membranous and becomes translucent in pre-dissection KOH treatment and readily collapses upon itself during scanning electron microscopy preparation, suggesting why it has been difficult to discern in previous studies.

The likely functions of the claws that we can discern are at least twofold, both of which are mechanical in nature and likely to be generating inter-locus sexual conflict [6]. One is that the claws serve to assist the male in achieving copulation by facilitating the grasping of the female and opening or orienting her gonopore—ability to 'coerce' previously inseminated females to mate may be an especially important determinant of male post-copulatory fitness [31,32]. A second potential (non-mutually exclusive) function is that they serve to anchor the genitalia and maintain intimate connection during copulation, thus facilitating the eversion of the aedeagus through the female gonopore and ejaculate transfer. A key observation in this regard is the seepage of ejaculate from between a mating pair involving a cut male (electronic supplementary material, figure S2), suggesting that claw removal resulted in the backflow of ejaculate, consistent

with the anchoring hypothesis. We emphasize that additional experiments, which are beyond the scope of the present study, are needed to satisfactorily characterize the function of these remarkable structures now that we have demonstrated that they do not serve to traumatically inseminate females. Here, our primary objective was to address the TI hypothesis, and our results have led us to reject the assertion that TI occurs in the *Drosophila bipectinata* species complex.

Data accessibility. Data are available on Mendeley Data [33] and in the electronic supplementary material.

Authors' contributions. M.P.: conceptualization, funding acquisition, investigation, methodology, writing—original draft, writing—review and
