ABSTRACT

Background: Among over 100 types of *Herpesviridae* viruses, eight can infect humans: herpes simplex viruses (HSV-1, HSV-2), varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesviruses 6, 7, and 8 (HHV-6, HHV-7, HHV-8). After initial infection, the viruses remain latent for the lifetime of the host. The aim of this study was to determine the distribution of six different herpesviruses: HSV-1, HSV-2, VZV, EBV, CMV, and HHV-6 in trigeminal and facial nerve ganglia among a random group of Polish population.

Methods: The studied group consisted of 47 individuals (40 male, seven female); mean age of 47.4 ± 16.5 years) who died of independent causes (suicide, traffic accident, and poisoning, among others). Bilateral trigeminal and facial nerve ganglia of each cadaver were collected during the autopsy. Herpesviruses were detected using multiplex polymerase chain reaction technique.

Results: Herpesviruses were found in trigeminal and/or facial ganglia in 30/47 (63.8%) of cadavers. HHV-6 was the most prevalent of the herpesviruses and was found in nearly half of cadavers ($n = 22$; 46.8%), followed by HSV-1 ($n = 7$; 14.9%), VZV ($n = 4$; 8.5%), EBV ($n = 4$; 8.5%), HSV-2 ($n = 2$; 4.3%), and CMV ($n = 1$; 2.1%). Facial nerve ganglia ($n = 23$; 48.9%) were more often infected than trigeminal ganglia ($n = 13$; 27.7%).

Discussion: The results of this study have revealed a common presence of the herpesviruses in trigeminal and facial nerve ganglia among a random group of Polish population. Furthermore, the data also demonstrate simultaneous infection of the ganglia with different herpesviruses. This study has contributed to the knowledge of prevalence and localization of herpesviruses in different structures of the nervous system.

INTRODUCTION

There are over 100 known herpesviruses, among which eight infect humans: herpes simplex viruses type 1 and 2 (HSV-1 and HSV-2), varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesviruses 6, 7, and 8 (HHV-6, HHV-7, HHV-8). Following primary infection, herpesviruses enter a dormant state and remain in the host for a lifetime (*Kinchington et al., 2012*). It has been reported that most of the human herpesviruses establish latency by forming an extrachromosomal episome, repressing viral replication and limiting gene expression. However, the exact mechanism varies depending on a virus, for example, HHV-6A integrates into the telomeric region of host chromosomes rather than forming episomes (*Pantry & Medveczky, 2017*). Herpesviruses are divided into three subfamilies (α , β , γ) based on their biological properties and tropism for different types of host cells. The alphaherpesviruses (HSV-1, HSV-2, VZV) stay dormant in neurons, gammaherpesviruses (EBV, HHV-8) establish latency within immune system cells (mainly B-cells) and betaherpesviruses (CMV, HHV-6) remain latent in hematopoietic cells (*White, Beard & Barton, 2012*; *Bloom, Giordani & Kwiatkowski, 2010*). Most of the initial infections are asymptomatic and occur in childhood (*White, Beard & Barton, 2012*; *Bloom, Giordani & Kwiatkowski, 2010*). Persistence and latency of alphaherpesviruses have been well demonstrated in human trigeminal, facial, and vestibular ganglia. Reactivation of the HSV in these ganglia has been associated with various disorders such as herpes labialis, Bell's palsy and vestibular neuritis (*Theil et al., 2002*). Furthermore, it has also been postulated that the virus may be spread from trigeminal ganglia to brain parenchyma and produce encephalitis (*Bradshaw & Venkatesan, 2016*). VZV reactivation may have various manifestations including shingles (herpes zoster) with classic vesicular rash, dermatomal pain syndromes without rash (zoster sine herpete), neuropathy or even encephalitis (*Gilden et al., 2010*). EBV, CMV, and HHV-6 may also have neurotropic potential and have been implicated in numerous neurological conditions, such as meningitis, encephalitis, cranial, or peripheral neuritis. The possible association between primary malignancies of central nervous system and herpesviruses has also been described (*Strojnik, Duh & Lah, 2017*; *Meyding-Lamadé & Strank, 2012*). Herpesviruses can reactivate in both immunocompetent and immunocompromised hosts. However, the risk of some life-threatening complications, such as disseminated zoster due to VZV reactivation or lymphoproliferative disease caused by EBV is greater among immunocompromised individuals (*Malaiya et al., 2015*). The most important immune defense against viral infections is the cell-mediated response with a crucial role of T-cells. Alterations in T-cell function and level are of particular relevance for latent viruses reactivation. The cellular immunity, in contrast to the humoral one, decreases with age, giving the opportunity for virus reactivation in elderly people (*White, Beard & Barton, 2012*). As most humans are supposedly infected with multiple herpesviruses, the risk of virus reactivation and possible complications, especially if immunosuppression occurs, is significant. Multiple studies have concentrated on the presence of HSV-1, HSV-2, and VZV in cranial nerve ganglia, but there is limited data about the occurrence of EBV, CMV, and

HHV-6 in these ganglia (Saitoh *et al.*, 2013; Motani *et al.*, 2006; Richter *et al.*, 2009; Hill *et al.*, 2008; Vrabec & Payne, 2001; Inoue *et al.*, 2010; Cohrs, Barbour & Gilden, 1996; Furuta *et al.*, 1992, 1997; Hüfner *et al.*, 2007). The aim of this study was to determine the distribution of six different herpesviruses: HSV-1, HSV-2, VZV, EBV, CMV, and HHV-6 in trigeminal and facial nerve ganglia of the individuals who died of independent causes.

MATERIAL AND METHODS

The studied group consisted of 47 individuals (40 male, seven female; mean age of 47.4 ± 16.5 years) who died due to independent reasons (suicide, traffic accident, and poisoning, among others). The study was approved by the Bioethical Committee of the Medical University of Białystok (R-I-002/360/2015). The material used in the study was collected as a part of a mandatory panel of samples secured during forensic autopsy in the Forensic Medicine Department at the Medical University of Białystok. Informed consent from the next of kin for autopsy and collection of the samples was not required due to obligatory nature of the forensic autopsy. Bilateral trigeminal and facial nerve ganglia were collected during the autopsy and divided into small fragments. Samples were stored in sterile eppendorfs and frozen at -20 °C.

Methods—DNA extraction

DNA was extracted by using the Qiagen DNAeasy Blood and Tissue Mini kit with spin columns according to manufacturer's instructions. Purified DNA isolates (200 μ l) of left and right particular cranial nerve were combined in one probe and were frozen at -20 °C before the time of amplification.

Methods—Herpesviruses (HSV-1, HSV-2, VZV, EBV, CMV, HHV-6) PCR detection

For simultaneous HSV-1, HSV-2, VZV, EBV, CMV, and HHV-6 molecular detection *The Seeplex Meningitis-V1 ACE Detection [V2.0] PCR kit* (Seegene, Seoul, Korea) for in vitro diagnostic was used (IVD CE mark). Highly conservative genes of HSV-1, HSV-2, VZV, EBV, CMV, and HHV-6 were simultaneously detected using one-tube multiplex PCR method. The kit used in the study is based on a concept of oligo technology—dual priming oligonucleotide (DPO™, Seegene, Seoul, South Korea) technology. DPO technology maximizes PCR specificity and sensitivity and optimizes amplification by fundamentally blocking non-specific priming. For control of nucleic acid extraction procedure and to check eventual inhibition of PCR amplification in clinical samples collected from patients, Internal Control (IC) was introduced into each amplification reaction and was co-amplified with target nucleic acid from the specimen. Addition of the 8-methoxypsoralen (MOP-8) was used to extinguish the template activity of contaminated DNAs and eliminate carry-over contamination.

Amplification was performed on the SensoQuest LabCycler (SensoQuest, Göttingen, Germany) in compliance with *Seegene* instructions. PCR Mastermix contained 10 μ l of Multiplex Master Mix (DNA polymerase and buffer with dNTPs), two μ l of MOP-8, two μ l of 10 \times MB ACE PM (Primer Mixture—primer pairs for six viral pathogens and

for IC), and one μl of IC. A five μl of the template DNA extract from nerve ganglia was added to 15 μl of the Mastermix for final reaction mix volume of 20 μl . The course of the amplification was prepared according to the following reaction program: initial denaturation at 94 °C for 15 min, amplification for 40 cycles: denaturation at 94 °C for 30 s, annealing at 63 °C for 90 s, extension at 72 °C for 90 s, and final extension at 72 °C for 10 min.

During 120 min of electrophoresis at 90 V, amplification products were separated on 2% agarose gel (Sigma-Aldrich, Darmstadt, Germany) containing Midori Green DNA Stain (Nippon Genetics, Tokyo, Japan). Amplicons were visualized by means of UV illumination in Gel Logic 100 Imaging System (Kodak, Rochester, NY, USA). Positive samples were those with amplification products with the length of 189 bp for HSV-1, 308 bp for HSV-2, 251 bp for VZV, 400 bp for EBV, 590 bp for CMV, 482 bp for HHV-6. Additionally, 1,000 bp long fragments of internal standard were detected in all samples. Results were compared with positive control (mixture of six viruses clones) provided in the detection kit. Negative control (sterilized water) which replaced template DNA was also provided by the manufacturer. Molecular weight markers (M100-M500, M100-1000-Blirt S.A. Poland), as well as MV2ACE Marker (provided), were used for each electrophoresis phase on an agarose gel to identify the approximate size of the target product.

RESULTS

Herpesviruses were detected in trigeminal and/or facial nerve ganglia in 30/47 (63.8%) of cadavers. HHV-6 was the most prevalent of herpesviruses and was found in nearly half of cadavers ($n = 22$; 46.8%) in analyzed samples, followed by HSV-1 ($n = 7$; 14.9%), VZV ($n = 4$; 8.5%), EBV ($n = 4$; 8.5%), HSV-2 ($n = 2$; 4.3%), and CMV ($n = 1$; 2.1%). Herpesviruses were detected in 23/47 (48.9%) samples of facial nerve ganglia and 13/47 (27.7%) of trigeminal ganglia. In the trigeminal ganglia of three cadavers, simultaneous presence of multiple herpesviruses was found: EBV/HHV-6 in one case and VZV/HHV-6 in two cases. Moreover, dual infection was also found in five samples of facial nerve ganglia: HSV-1/HHV-6 in two cases and isolated cases of HSV-2/EBV, VZV/CMV, and EBV/HHV-6 co-presence. Simultaneous occurrence of different herpesviruses was found in trigeminal and facial nerve ganglia. In four cases the same virus was present both in trigeminal and facial nerve ganglia.

Basic information about cadavers and presence of herpesviruses in trigeminal and facial ganglia of each individual are provided in [Table 1](#). Prevalence of each herpesvirus in trigeminal and facial ganglia is shown in [Table 2](#). The results of electrophoretic detection of herpesviruses PCR products amplification are shown in [Figs. 1–7](#).

DISCUSSION

Herpesviridae is a large group of enveloped, double-strained DNA viruses.

The characteristic feature of all herpesviruses is their ability to stay dormant within a cell generating a lifelong latent infection in their hosts ([Bloom, Giordani & Kwiatkowski, 2010](#)). Herpesviruses are widespread among the human population. Wide variation in

seroprevalence of herpesviruses has been observed in different European countries which can be the result of varying population densities, social mixing and climate differences (Galdiero et al., 2018). Some studies suggest that seroprevalence of certain herpesviruses may be higher in urban populations than in the rural populations, while others do not support this finding (Lolekha et al., 2001; Cunningham et al., 2006; Siennicka et al., 2009). In a study carried out by Smith et al. (2006), the overall seropositivity rate for HSV-1 and HSV-2 in four geographic regions in Poland was 90.4% and 9.3%,

respectively. *Siennicka et al. (2009)* reported that seropositivity rate for VZV was approximately 98% in a group of 19-year-olds from Poland. The same author conducted a study among women of childbearing age, where the overall anti-CMV IgG seropositivity was 81.9% (*Siennicka et al., 2016*). Data regarding seroprevalence of other herpesviruses in general population in Poland is limited.

HSV-1 is widespread throughout the world and establishes latency in sensory ganglia. In the study conducted by *Saitoh et al. (2013)*, the trigeminal ganglia obtained from

12 human cadavers submitted for forensic autopsy within 1–5 days of death were cultured over a layer of Vero cells in order to evaluate whether the virus in the ganglia of the cadavers could be reactivated. It was demonstrated that viable HSV-1 persists in human trigeminal ganglia for some time after death. The presence of HSV-1 detected by PCR in trigeminal human ganglia was found by *Motani et al. (2006)* in almost 65% of 207

human cadavers and in 60% of these cadavers, the presence was bilateral. In a study conducted by [Richter et al. \(2009\)](#), the distribution of HSV-1 in head and neck ganglia was evaluated and presence of the virus was detected in trigeminal, facial, and many other, both sensory and autonomic, ganglia. Overall, 36% of the analyzed samples were positive for HSV-1 DNA in this study. The results suggest that HSV-1 latency extends beyond the trigeminal nerve ganglia and the virus may reactivate from non-trigeminal site causing atypical presentation. In research carried out by [Hill et al. \(2008\)](#), HSV-1 was found in 155/174 (90.1%) trigeminal ganglia of investigated subjects. [Vrabec & Payne \(2001\)](#) studied trigeminal, geniculate, vestibular, spiral, and vagal ganglia of 18 cadavers and detected HSV DNA in 42% of surveyed ganglia. The aforementioned studies, similarly to our study, were performed on random individuals with no active HSV infection at the time of death. In our study, HSV-1 was found both in the facial nerve ganglia and trigeminal ganglia. HSV-1 DNA was present in 7/47 (14.9%) of cadavers. Furthermore, simultaneous presence of HSV-1 and HHV-6 in the same or different ganglia was found in three cadavers in our study.

HSV-2 reactivates predominantly from lumbar-sacral ganglia giving rise to recurrent genital disease (*Margolis et al., 2007; Lafferty et al., 1987*). However, HSV-2 has been also implicated in oral-labial infections and may also cause meningitis or encephalitis (*Lafferty et al., 1987; Moon et al., 2014*). In a study carried out by *Richter et al. (2009)*, superior cervical ganglion, nodose ganglion, pterygopalatine ganglion, ciliary ganglion, otic ganglion, submandibular ganglion, and geniculate ganglion did not manifest any trace of HSV-2. In the present study, HSV-2 DNA was found in two samples of facial nerve ganglia but was not detected in trigeminal ganglia. In one cadaver, HSV-2 DNA coexisted with EBV DNA detected in trigeminal and facial nerve ganglia.

Varicella zoster virus establishes latency in the sensory ganglia after primary infection and the viral DNA is found mainly in trigeminal, geniculate, and thoracic ganglia. Human trigeminal ganglia are commonly dually infected with HSV-1 and VZV (*Theil et al., 2002*). Numerous studies were undertaken to assess VZV prevalence in the head and neck ganglia. In a study carried out by *Inoue et al. (2010)*, VZV was detected in 94.4% (in 97.1% cadavers) of trigeminal ganglia and HSV-1 was found in 60.6% of trigeminal ganglia (in 64.7% cadavers). In an examination of human trigeminal ganglia performed by *Cohrs, Barbour & Gilden (1996)*, VZV was detected in all samples and HSV-1 was found in 72.7% samples from 25 cadavers. In a study conducted by *Richter et al. (2009)* 22/36 (61%) of cadavers had VZV DNA in at least one ganglion and overall, there were more HSV-1-positive samples than VZV-positive samples (36% vs. 18%). In our study, HSV-1 DNA was found in more samples than VZV, both in trigeminal and facial nerve ganglia. In a study carried out by *Vrabec & Payne (2001)*, VZV was detected in 64/144 (44%) of studied cranial nerve ganglia. *Furuta et al. (1992)* detected VZV DNA in 9/13 (69.2%) of examined geniculate ganglia and 11/14 (78.6%) of trigeminal ganglia of adults with no history of recent infection (chickenpox or shingles). In the subsequent study by the same author, VZV DNA was detected in 2/10 (20%) of vestibular ganglia and in 2/10 (20%) of spiral ganglia from five adults (*Furuta et al., 1997*). In our study VZV was detected in 4 (8.5%) of cadavers.

After primary infection, EBV establishes latency within B-cell pool. Beyond mononucleosis, the best known clinical manifestation of EBV, other conditions have been associated with primary infection, such as hematologic abnormalities or neurologic syndromes (*Tselis et al., 1997; Patil et al., 2012; Celik et al., 2015*). Although EBV has been linked mostly with lymphoproliferative disease in immunosuppression (such as Burkitt's lymphoma, Hodgkin's disease, T-cell lymphomas, nasopharyngeal carcinoma), the virus can affect virtually any organ and cause a wide range of disease manifestations (e.g., pneumonia, myocarditis, pancreatitis, mesenteric adenitis, myositis, and glomerulonephritis) (*Young & Murray, 2003*). Cases of encephalitis, encephalomyelitis, chronic meningitis, and central nervous system vasculopathy due to EBV infection have been reported (*Tselis et al., 1997; Patil et al., 2012; Celik et al., 2015*). Bell's palsy is most commonly associated with HSV and VZV, but other *Herpesviridae*, such as EBV and CMV may also cause acute peripheral facial palsy (*McFarlin & Peckler, 2008*). Moreover, EBV has been linked to other neurological pathologies, including multiple sclerosis, primary central nervous system lymphoma, Alzheimer's disease, and cerebellar ataxia.

The association of these diseases with EBV was largely based on the presence of high EBV titers in cerebrospinal fluid samples from the patients. However, there is evidence that EBV can directly infect neurons and therefore may be a potential factor in the pathogenesis of these conditions. In *in vitro* studies, EBV undergoes a predominantly lytic replication in neuronal cells ([Jha et al., 2015](#)), but perhaps it may also establish latency in neurons. We have not found any studies describing presence of EBV in trigeminal or facial ganglia. In our study, EBV was present in 4/47 (8.5%) cadavers in trigeminal and/or facial ganglia.

Cytomegalovirus is a common virus with seroprevalence rates varying from 45% to 100% of the adult population ([Cannon, Schmid & Hyde, 2010](#)). CMV infection is also the most frequent congenital viral infection which has been associated with permanent neurological impairment, including cerebral palsies, sensorineural hearing loss and neurodevelopmental abnormalities. Primary CMV infection is followed by viral latency and possibility of reactivation ([Chavanas, 2016](#)). CMV is known to cause encephalitis and multiple cranial nerve palsies in immunocompromised ([Karna et al., 2001](#)). Studies investigating permissiveness of neurons to CMV infection *in vitro* have led to conflicting results. Although primary mature human neurons showed no antigen expression or cytopathic effect after *in vitro* infection, neurons derived from human neural progenitor cells prepared from fetus have been reported to be permissive to CMV infection in some studies. Furthermore, it has been demonstrated that murine CMV is able to establish latency in neural stem progenitor cells and reactivate in mouse brain slice culture ([Chavanas, 2016](#)). In our study, CMV was present in the facial nerve ganglia in one cadaver but was absent in trigeminal ganglia.

The primary HHV-6 infection of adults is relatively rare. The virus infects mostly children in the first two years of life, presenting as roseola ([Zerr et al., 2005](#)). Seroprevalence rate of HHV-6 ranges from 52% to over 90% in some studies ([Cone et al., 1993](#)). HHV-6 has been demonstrated to be neurotropic and is able to persist in a latent form in the nervous system, where it can reactivate, causing wide spectrum of neurological manifestations. Since its discovery, HHV-6 has been implicated in the development of a wide array of neurological conditions, such as seizures, encephalitis, mesial temporal lobe epilepsy, and multiple sclerosis. In recent years HHV-6 has become an increasingly recognized cause of post-transplant limbic encephalitis. It has also been associated with encephalitis in adult immunocompetent patients and is likely to be underdiagnosed as a cause of encephalitis ([Ogata, Fukuda & Teshima, 2015](#); [Yilmaz et al., 2018](#)).

In a study conducted by [Harberts et al. \(2011\)](#), distribution of HHV-6 in different anatomical locations of central nervous system was evaluated. The authors have demonstrated that frequency of HHV-6 in the olfactory bulb/tract (50%) was among the highest in the brain regions examined. Furthermore, they confirmed that nasal cavity is a reservoir of HHV-6 and that specialized olfactory-ensheathing glial cells located within the nasal cavity support HHV-6 replication *in vitro*, which provides evidence for the hypothesis that HHV-6 may enter the central nervous system via olfactory pathway. [Hüfner et al. \(2007\)](#) detected HHV-6 in 30% of trigeminal, 40% of geniculate, 25% of

vestibular, and 55% of dorsal root ganglia. Furthermore, in their research, HHV-6 was found to co-occur with HSV-1 or VZV in 91% of ganglia. In a study conducted by [Chapenko et al. \(2016\)](#), the authors evaluated frequency of HHV-6 and HHV-7 genomic sequences in central nervous system DNA samples from post-mortem individuals with unspecified encephalopathy. A significantly higher frequency of single HHV-6 and HHV-6 with HHV-7 was found in pia mater meninges, frontal lobe, temporal lobe, and olfactory tract DNA in individuals with encephalopathy than in a control group. Among all of the viruses included in our study, HHV-6 was the most commonly detected virus and was found in almost half of cadavers (46.8%) with a predominance in the facial nerve ganglia. Other herpesviruses (VZV, EBV, HSV-1) have been found to co-occur with HHV-6 in 6/23 (26.1%) samples of the HHV-6 positive ganglia. HHV-6 is possibly one of the first herpesviruses to infect the ganglia and it has been speculated whether latent HHV-6 infection of the ganglia could create an environment which facilitates the invasion of the other herpesviruses ([Hüfner et al., 2007](#)).

The limitation of this study was a relatively small sample size, which could be enlarged in further studies for better assessment of herpesviruses' distribution in nerve ganglia.

CONCLUSIONS

The results of this study have revealed a common presence of latent form of six herpesviruses among a random group of Polish population. All of the herpesviruses described in this article have neurotropic potential. Surprisingly, the presence of the viral DNA was observed in higher frequency in facial nerve ganglia than in trigeminal ganglia (48.9% vs. 27.7%). HHV-6 was the most prevalent of all herpesviruses in our study. The data also demonstrated simultaneous infection of the ganglia with different herpesviruses. Although presence of HSV-1, HSV-2, and VZV in various nerve ganglia has been well described, a limited number of studies have been undertaken to assess the presence of EBV, CMV, and HHV-6 in cranial nerve ganglia. This study has contributed to the scope of observations made in relation to the frequency and localization of herpesviruses in different structures of the nervous system.

ADDITIONAL INFORMATION AND DECLARATIONS

Funding

This study was funded by Medical University of Białystok, Poland (Grant No. N/ST/ZB/16/003/1121). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Grant Disclosures

The following grant information was disclosed by the authors:
Medical University of Białystok, Poland: N/ST/ZB/16/003/1121.

Competing Interests

The authors declare that they have no competing interests.

Author Contributions

- Iwona Ptaszyńska-Sarosiek conceived and designed the experiments, performed the experiments, analyzed the data, contributed reagents/materials/analysis tools, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.
- Justyna Dunaj conceived and designed the experiments, performed the experiments, analyzed the data, contributed reagents/materials/analysis tools, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.
- Agata Zajkowska analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.
- Anna Niemcunowicz-Janica conceived and designed the experiments, contributed reagents/materials/analysis tools, authored or reviewed drafts of the paper, approved the final draft.
- Monika Król analyzed the data, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.
- Sławomir Pancewicz conceived and designed the experiments, contributed reagents/materials/analysis tools, authored or reviewed drafts of the paper, approved the final draft.
- Joanna Zajkowska conceived and designed the experiments, analyzed the data, contributed reagents/materials/analysis tools, prepared figures and/or tables, authored or reviewed drafts of the paper, approved the final draft.

Human Ethics

The following information was supplied relating to ethical approvals (i.e., approving body and any reference numbers):

The study was approved by the Bioethical Committee of the Medical University of Białystok (R-I-002/360/2015).

Data Availability

The following information was supplied regarding data availability:

The raw data is provided in [Supplementary File](#).

Supplemental Information

Supplemental information for this article can be found online at <http://dx.doi.org/10.7717/peerj.6095#supplemental-information>.
