Ribosomopathy-associated mutations cause proteotoxic stress that is alleviated by TOR inhibition

Abstract

Ribosomes are multi-component molecular machines that synthesize all the proteins of living cells. Understandably, most genes encoding the protein components of ribosomes are essential. Reduction in gene dosage is often viable but deleterious and associated with human syndromes, collectively known as ribosomopathies [1–3]. The cell biological basis of these pathologies has remained unclear. Here, we model human ribosomopathies in *Drosophila* and find widespread apoptosis and cellular stress in the resulting animals. This is not caused by insufficient protein synthesis, as reasonably expected. Instead, ribosomal protein deficiency elicits proteotoxic stress, which, we suggest, is caused by the accumulation of misfolded proteins that overwhelm the protein degradation machinery. We find that dampening the integrated stress response [4] or autophagy worsens the harm inflicted by ribosomal protein deficiency, suggesting that these activities could be cytoprotective. Inhibition of TOR activity, which dampens ribosomal protein production, slows down protein synthesis and stimulates autophagy [5], reduces proteotoxic stress in our ribosomopathy model. Interventions that stimulate autophagy, combined with means of boosting protein quality control, could form the basis of a therapeutic strategy for this class of diseases.

Keywords

ribosomes; protein translation; ribosomopathies; proteotoxic stress; autophagy; protein aggregates; apoptosis; p62; eIF2; TOR; RPS23; RPS26; Diamond Blackfan anemia

Ribosomopathies encompass a wide range of syndromes. Common symptoms include a reduced number of blood cells, predisposition to cancer, skeletal abnormalities, and growth retardation [1–3]. Neurological defects are also observed, though less frequently [1,6–8]. A subset of these symptoms including growth retardation and mild autism, but not anemia, were recently reported for a child carrying a *de novo* mutation in a gene encoding a component of the 40S subunit (RPS23[R67K]) [9,10]. Upon the request of this patient's father, we introduced this mutation in *Drosophila* and characterised the resulting phenotype. We used CRISPR/Cas9 to replace the third exon by a version encoding the R67K substitution (Fig. 1a). Adult heterozygous ($RPS23^{R67K/+}$) animals were viable and fertile but displayed the phenotype associated with all the haplo-insufficient genes encoding ribosomal proteins (RPs), collectively known as *Minute* genes [11,12]. Thus, scutellar bristles of $RPS23^{R67K/+}$ adults were shorter than those of wild type animals and mutant larvae were developmentally delayed (Extended data Fig. 1a-c). Another characteristic of *Minute*$^{+/-}$ cells is that, in genetic mosaics, they are eliminated by surrounding wild type cells, a process known as cell competition [13]. This effect is readily assayed in fast growing larval epithelial structures called wing imaginal discs [14,15]. We found that, in mosaic imaginal discs, $RPS23^{R67K/+}$ cells were outcompeted by wild type cells and that this was accompanied by a high rate of apoptosis, as indicated by Dcp1 immunoreactivity (Extended data Fig. 1d, e). These findings suggest that $RPS23^{R67K}$ behaves like a classical *Minute* mutation. Therefore, although the patient's mutation is the starting point of this study, it is expected to trigger the same cell biological response as other ribosomopathy-associated mutations.

Cell competition involves short range interactions that enable wild type cells to trigger apoptosis in *Minute*$^{+/-}$ cells [14]. However, we found that apoptotic figures were widespread in wholly heterozygous $RPS23^{R67K/+}$ imaginal discs, much more so than in wild type disc [16] (Fig. 1b-f). This observation suggests that $RPS23^{R67K/+}$ cells undergo apoptosis independently of any signal from wild type cells. This is not a peculiarity of this mutation since *RPS3* and *RPL14* heterozygotes have been reported to undergo widespread apoptosis, as assayed by TUNEL staining [17]. Adding to this evidence, we found that imaginal discs lacking one copy of *RPS13*, *RPL5* or *RPL14* had numerous Dcp1-positive cells (Extended data Fig. 1h-j). It is clear therefore that RP-deficient cells undergo apoptosis in a cell competition-independent manner. To confirm that this effect is tissue intrinsic, we generated a conditional allele of *RPS26* (Fig. 1g), a gene associated with Diamond Blackfan anemia [18]. Inactivation of one homolog in the posterior half of the discs, leaving the rest of the animal genetically wild type, only triggered apoptosis in the heterozygous region (Fig. 1h, i), implying that a systemic signal is not involved.

The high rate of apoptosis in *Minute* heterozygotes suggests that these cells are intrinsically stressed. This is consistent with the widespread activation of JNK signalling that has been reported in *RPS3*$^{+/-}$ and *RPS15*$^{+/}$ imaginal discs [19], an observation that we confirmed in $RPS23^{R67K/-}$, $RPL5^{+/-}$, $RPL14^{+/-}$, and $RPS13^{+/-}$ imaginal discs (Extended data Fig. 1f-j). Another characteristic of *Minute* mutant cells is that they upregulate Xrp1, a protein recently shown to be required for cell competition [20–22], and associated with the response to oxidative stress [23] and DNA damage response [21]. We found that the rate of apoptosis in $RPS23^{R67K}$ heterozygous tissues was strongly reduced by knocking down Xrp1 (Extended data Fig. 2). Therefore, Xrp1 is an essential component of the response to the cellular stress

caused by RP deficiency, irrespectively of cell competition. Overall, the above considerations and additional observations in other models of ribosomopathies [1,2,24] show that apoptosis and cellular stress are a characteristic response to RP deficiency.

What could be the proximal cause of stress and apoptosis in RP-deficient tissue? Wing precursors undergo about 1000-fold increase in tissue size during larval development [25,26] and it is conceivable that a limited number of functional ribosomes might not suffice to meet the associated protein demand. Protein synthesis has indeed recently been shown to be depressed in RP-deficient cells [20]. We therefore asked whether this is also true in $RPS23^{R67K/+}$ and $RPS26^{KO/+}$ tissue. We generated imaginal discs with one half heterozygous mutant and the other half genetically wild type, as an internal control. These imaginal discs were explanted and bathed in 1 μM O-propargyl-puromycin (OPP), for 15 minutes. A click-chemistry reaction was then used to visualise puromycilated peptides in situ [27]. Incorporation was reduced in both $RPS23^{R67K/+}$ and $RPS26^{KO/+}$ cells relative to that in the control wild type territory (Fig. 1j, k), confirming that the rate of protein synthesis is indeed depressed in these two conditions. However, as argued below, this is unlikely to be the cause of cellular stress.

To experimentally alter the rate of protein synthesis, we took advantage of genetic tools that modulate Target of Rapamycin (TOR), a master regulator of translation and ribosome biogenesis [5]. Expression of an RNAi transgene against Rheb, a TOR activator, led to reduced OPP incorporation while Rheb overexpression led to increased incorporation (Extended data Fig. 3). Rheb knockdown in the anterior compartment was associated with tissue size reduction, as expected. However, this was not accompanied by increased apoptosis (Fig. 1l). Conversely, stimulation of TOR signalling by Rheb overexpression did not prevent, and even possibly enhanced, apoptosis in RP deficient tissue (Fig. 1m). These results indicate that, while translation is depressed in RP-deficient cells, this is unlikely to be the trigger of apoptosis in these cells. In fact, $RPS23^{R67K/+}$ cells do not appear to be limited in their capacity to produce proteins since, upon inhibition of apoptosis, they gave rise to tumours, hence generating biomass (Extended data Fig. 4).

In the course of optimizing the conditions for OPP incorporation, we noticed that, at high doses and/or extended incorporation times (e.g. 20 μM, 30 min), the OPP signal accumulated preferentially in $RPS23^{R67K/+}$ or $RPS26^{KO/+}$ tissue by comparison to the wild type territory (Fig. 2a, b). This counterintuitive observation can be rationalised if one considers the fact that puromycin causes premature translation termination in a dose-dependent manner, with the resulting truncated polypeptides often failing to fold properly [28]. These defective ribosomal products (DRiPs) are normally recognised and cleared by the ubiquitin-proteasome system (UPS) and autophagy [29,30]. However, under conditions of impaired protein quality control response, the burden caused by OPP treatment becomes overwhelming and puromycilated DRiPs accumulate in aggregates [31]. Interestingly, puromycilated polypeptides accumulated in large punctae upon high dose of OPP (20 μM, 30 min) and this was much more pronounced in the mutant compartment ($RPS23^{R67K/+}$ or $RPS26^{KO/+}$) than in the control tissue. This observation suggests that the disposal of misfolded proteins could be impaired in RP-deficient tissue.

To further test the ability of RP-deficient cells to face proteotoxic stress, we assessed how they handle an aggregation-prone protein. Huntington disease is characterised by polyglutamine (polyQ) expansion in the Huntingtin protein (HTT), which, over a threshold length (>36Q), promotes the formation of oligomers and aggregates [32]. Shorter glutamine stretches are not considered pathogenic but the behaviour of sub-pathological HTT25Q could provide an indication of a cell's competence to mount a response to proteotoxic stress [33,34]. As expected, the fluorescence of HTT25Q-Cerulean in otherwise wildtype tissue was largely homogeneous, with only a few small clusters (Fig. 2c). However, in the $RPS23^{R67K/+}$ background, this protein accumulated in large punctae (Fig. 2d, **quantified in 2e**). These observations suggest that RP-deficient cells are less able than their wild type counterparts in preventing the accumulation of aggregate-prone species such as truncated OPP-peptides or polyQ repeats. Expression of HTT96Q in an otherwise wild type background leads to excess apoptosis (Extended data Fig. 5), indicating that even wild type cells cannot overcome a large number of repeats. We conclude that proteotoxic stress suffices to trigger apoptosis and that RP-deficient cells are more readily overwhelmed by such stress than wild type cells.

Hallmarks of proteotoxic stress include increased ubiquitination, which targets proteins for degradation, stimulation of autophagy, and enlargement of lysosomes. Ubiquitination, assayed with an antibody, was higher in $RPS23^{R67K/+}$ than in control tissue (Fig. 2f, g). The p62 protein, AKA SQSTM1 or Sequestosome-1, a ubiquitin-binding adaptor that functions both as a receptor and cargo for selective autophagy [35], also accumulated specifically in $RPS23^{R67K/+}$ (Fig. 2h, i) as well as in $RPS26^{KO/+}$ cells (Extended data Fig. 6a). A similar accumulation could be seen in human cells (HEK293) engineered by CRISPR/Cas9 to carry this mutation ($RPS23^{R67K/R67K}$) (Figure 2j, k, **quantified in 2l**). Correspondingly, the lysotracker-labelled acidic compartment, a proxy for lysosomes, was enlarged in the $RPS23^{R67K/+}$ territory (Fig. 2m), suggesting a high load on autophagy. To further assess autophagy, we took advantage of a dual-colour GFP-mCherry-Atg8a reporter [36], which marks autophagosomes and autolysosomes by virtue of the differential sensitivity of GFP and mCherry to acidification (Extended data Fig. 7a). Both markers were increased in $RPS23^{R67K/+}$ imaginal discs, suggesting altered progression through the autophagic pathway (Extended data Fig.7 b, c). This observation, combined with the accumulation of p62-positive punctae (Fig. 2 h, i), indicates that, upon RP deficiency, ubiquitinated substrates exceeds the cell's degradative capacity, a situation likely to cause proteotoxic stress. Proteotoxic stress, and the ensuing integrated stress response (ISR), is manifest by phosphorylation of the eukaryotic initiator factor 2 alpha (eIF2α). To ask if the ISR is activated in RP-deficient cells, we stained imaginal discs with an antibody against phosphorylated eIF2α (P-eIF2α). The signal was distinctly higher in $RPS23^{R67K/+}$ and $RPS26^{KO/+}$ tissues than in the control half of the discs (Fig. 2n; Extended data Fig. 6b). We conclude therefore that RP-deficient cells experience proteotoxic stress and activate the ISR as a result.

Proteotoxic stress arises from the accumulation of misfolded proteins and/or the formation of protein aggregates. What could be the origin of such proteins in RP-deficient tissues? One can imagine that, in the absence of one functional protein component, dysfunctional ribosomes form. These could be less conducive to co-translational folding and thus generate

an inordinate amount of unfolded proteins [37]. Alternatively, abnormal stoichiometry of ribosomal proteins could affect the translation of a subset of mRNAs and thus upset the relative amounts of different proteins [38], with excess proteins requiring additional degradation capacity. Yet another possibility is that partially functional ribosomes could be prone to making mistakes and hence produce misfolded proteins. Translational fidelity has indeed been reported to be reduced in cultured $RPS23^{R67K/+}$ fibroblasts [9]. To determine whether this is also the case in $RPS23^{R67K/+}$ animals, we generated transgenic flies expressing a stop codon readthrough reporter inspired by the design of Grentzmann and colleagues [39]. This comprised DNA encoding Firefly luciferase (Fluc) and Nanoluciferase (Nluc) separated by a tetranucleotide termination signal (UGAC) [40] and a flexible linker (Extended data Fig. 8a). Thus, Nluc luminescence is only expected if an amino acid is wrongly incorporated at the stop codon and the Nluc to Fluc ratio therefore provides an estimate of the rate of ribosomal mistakes. This reporter was validated in animals fed for 48h with G418, which causes stop codon readthrough [40]. Nevertheless, no difference in translational fidelity could be detected between wild type and $RPS23^{R67K/+}$ animals (Extended data Fig. 8b). We therefore considered the possibility, suggested by recent work in yeast, that imbalanced production of RPs leads to rapid aggregation of orphan RPs and acute loss of proteostasis [41,42].

Ribosomal proteins comprise a large proportion of cellular proteins; in humans, they represent about 6% of the proteome by mass [43–46]. In the absence of a single RP species, unassembled ribosomal proteins have a tendency to aggregate [47] and need to be disposed of since they could lead to proteotoxic stress [41,42,48]. To explore the possible contribution of orphan RPs to proteotoxic stress in RP-deficient tissues, we compared the proteome of $RPS23^{R67K/+}$ and wild type imaginal discs using label free mass spectrometry. In accordance with its role in stress response, IRBP18, the molecular partner of Xrp1 [49], was found to be upregulated in mutant discs (green dot in Fig. 3a; see all proteins highlighted in Supplementary Table 2, in supplementary information). Moreover, there was a general increase in the abundance of proteins involved in ribosome biogenesis (red dots), suggesting that RP-deficient tissues attempt to compensate for the loss of functional ribosomes by boosting their production. Ribosomal proteins themselves showed a differential response depending on the subunit that they contribute to. Large subunit RPs (blue circles) were over-represented in RPS23[R67K] heterozygotes, perhaps as a consequence of increased ribosome biogenesis. In contrast, small subunit RPs (orange circles) were under-represented, suggesting that they are degraded at an increased rate, as expected for ribosomal proteins that cannot participate in a complete subunit for lack of one functional component (Fig. 3b). The need to degrade orphaned small subunit RPs could place an unusually large burden on the protein degradation machinery and trigger proteotoxic stress. Although other models cannot be excluded, with the evidence currently at hand, we favour the notion that proteotoxic stress in RP-deficient tissues arise from unassembled ribosomal proteins that overload the protein degradation systems.

As shown above, RP-deficient cells respond to proteotoxic stress by stimulating the phosphorylation of eIF2α. We now address whether this response is maladaptive or cytoprotective. To reduce the P-eIF2α pool, we overexpressed the conserved GADD34 protein, a substrate-selective regulatory subunit of the catalytic protein phosphatase 1 (PP1)

[50]. As expected, GADD34 overexpression led to a drop in P eIF2α immunoreactivity in both wild type and $RPS23^{R67K/+}$ imaginal discs (Extended data Fig. 9a-d). In otherwise wild type, but not $RPS23^{R67K/+}$, animals, this was accompanied by a relatively minor but significant increase in tissue size (Extended data Fig. 9e-f). Crucially, GADD34 overexpression increased apoptosis by about three-fold in $RPS23^{R67K/+}$ tissue despite having no or little impact on the rate of apoptosis in wild type discs (Fig. 4a-d). Moreover, GADD34 overexpression led to an increase in the number of HTT25Q punctae in $RPS23^{R67K/+}$ discs (Extended data Fig. 9g-i). These observations suggest that the phosphorylated form of eIF2α contributes to limiting the proteotoxic stress caused by RP deficiency. We then addressed if autophagy is also part of a cytoprotective process. Expression of an RNAi transgene against Autophagy-related gene 1 (Atg1), which is required for autophagosome formation, had no detectable effect on the rate of apoptosis in otherwise wild type tissue (Fig. 4e, h). However, expression of the same $Atg1^{RNAi}$ transgene markedly enhanced the rate of apoptosis in RP-deficient cells (Fig. 4f-h). This implies that, conversely, stimulation of autophagy could dampen proteotoxic stress in RP-deficient cells. The contribution of the proteasome could not be unambiguously determined (Extended data Fig. 10a-c) for lack of suitable genetic tools. Likewise, the relative importance of mechanisms involving heat-shock proteins (HSPs), the unfolded protein response (UPR), and/or dampening of translation also remain to be assessed.

Having established that P-eIF2α and autophagy limits the toxic effects of RP deficiency, we sought to experimentally emulate their downstream effects, with the hope of opening therapeutic avenues. One signalling pathway, that mediated by TOR, stands out since it regulates many of the relevant processes, including autophagy, translation and ribosome biogenesis. To test if TOR inhibition could reduce proteotoxic stress and apoptosis in RP-deficient tissues, a RNAi transgene against Rheb was expressed in the anterior half of imaginal discs wholly heterozygous for $RPS23^{R67K}$. This led to a marked decrease in the rate of apoptosis (Fig. 5a, compare Dcp1 immunoreactivity to that in the control $RPS23^{R67K/+}$ half). Crucially, p62 immunoreactivity was also reduced in the 'rescued' compartment suggesting that improved cell survival resulted from a lessening of proteotoxic stress (Fig. 5b, b'). As an alternative means of inhibiting TOR, we introduced rapamycin in larval food. A 48h feeding period led to a 3-fold reduction in the rate of apoptosis in $RPS23^{R67K/+}$ imaginal discs (Fig. 5c, d, **quantified in 5e**). Therefore, reduction of TOR activity through two independent means alleviates the proteotoxic effect of RP deficiency. By virtue of inhibiting TOR, rapamycin could have multiple beneficial effects. By stimulating autophagy, it is expected to boost the removal of toxic species. By downregulating translation, it is predicted to lessen the burden on the protein degradation machinery [51] while at the same time allowing more time for co-translational folding [52,53]. And by dampening ribosome biogenesis, rapamycin would reduce the amount of orphaned ribosomal proteins. The relative importance of these processes remains to be assessed.

Our work suggests that unresolved proteotoxic stress, not insufficient protein production, could drive the pathology of ribosomopathies. Independent evidence for proteotoxic stress in RP-deficient cells is described in the accompanying paper [54], with attention to its relevance to cell competition. We found that, upon RP deficiency, proteotoxic stress triggers eIF2a

phosphorylation, which is known to slow down translation. Therefore, although the reduction in protein synthesis seen in RP-deficient tissues could be attributed to limited biosynthetic capacity, our findings suggest that it could equally follow from the response to proteotoxic stress. In any case, we have shown that P-eIF2α and autophagy are cytoprotective but insufficiently so. It is conceivable that cells cannot enhance this response further without triggering unacceptable side effects. We found that, to some extent, proteotoxic stress can be alleviated by TOR inhibition, an intervention that has been considered for proteinopathies, including Alzheimer's, Parkinson's, Amyotrophic lateral sclerosis, and Huntington's [55]. Although promising in our assays, rapamycin treatment should be seen as a proof of principle intervention since is unlikely to be appropriate for children or in tissues of high biosynthetic demand, where TOR activity is particularly important. Indeed, in fast growing Drosophila larvae, we have not been able to identify a rapamycin regimen that completely suppresses proteotoxic stress without impairing growth. There is a need therefore to specifically target the downstream activities of TOR that are most likely to alleviate proteotoxic stress, such as, for example, autophagy. In this respect it is of interest that a small-molecule inducer of autophagy enhanced erythropoiesis in models of Diamond-Blackfan anemia [56]. This could be combined with additional means of reducing proteotoxic burden, e.g. with drugs that favour protein folding or stimulate the clearance of misfolded proteins [57,58].

Methods

Drosophila stocks

All the genotypes analysed in this study are listed in Supplementary Table 1, in supplementary information. The following stocks were obtained from the Bloomington *Drosophila* Stock Center (BDSC), the Vienna Drosophila Resource Center (VDRC) or are described in Flybase: *ci-GAL4* (Flybase #FBti0076751), *hh-GAL4* (Flybase #FBti0017278), *rn GAL4* (BDSC #7405), *tub-GAL4* (BDSC #5138), *pdm2-GAL4* (BDSC #49828), *nub-GAL4* (Flybase #FBti0150342), *FRT42D* (BDSC #1802), *FRT42D ubi-GFP* (BDSC #5626), *TRE-GFP* (BDSC #59010), *UAS-GFP* (BDSC #35786), *UAS-FLP* (BDSC #4540), *UAS-P35* (Flybase #FBtp0001646), *UAS-HTT25Q Cerulean* (BDSC #58360), *UAS-HTT96Q-Cerulean* (BDSC #56772) *UAS-GFP-mCherry-Atg8a* (BDSC #37749), *UAS-Rheb* (BDSC #9688), *UAS-GADD34* (BDSC #76250), *UAS-Atg1^{RNAi}* (BDSC #44034), *UAS-Rheb^{RNA}* i (BDSC #33966), *UAS-Xrp1^{RNAi}* (BDSC #34521), *UAS Rpn2^{RNAi}* (VDRC #106457), *UAS-Rpt6^{RNA}* (VDRC #49244), *RPL5^{2d2}* (BDSC #25907), *RPL14^1* (BDSC #2247), *RPS13^1* (BDSC #2246), *Dp(2:3)Cam14T* (BDSC #4519).

Genomic engineering of flies and HEK293 cells

The *RPS23[R67K]* allele was generated by CRISPR/Cas9-mediated homologous directed repair. Suitable 5' and 3' homology arms, as well as the fragment carrying the R67K substitution, were cloned into the pTV attP-Pax-Cherry targeting vector [59] and gRNAs were cloned into the pCFD4 vector (Addgene #49411). The resulting plasmids were co-injected in a *nos-Cas9* strain [60]. Transgenic candidates were screened by *Pax-Cherry* expression and subsequently confirmed by PCR and sequencing.

The *RPS26[cKO]* (conditional KO) allele was generated in two steps. First, a *RPS26* knockout strain (*RPS26[attP-KO/+]*) was generated by replacing the second *RPS26* exon by an attP docking site. Suitable 5' and 3' homology arms were cloned into pTV-attP-Pax-Cherry and gRNAs into pCFD4. Positive *RPS26[attP KO]* heterozygous candidates were screened by the expression of *Pax Cherry* and validated by PCR. As expected, *RPS26[attP-KO/+]* flies displayed the so-called *Minute* bristle phenotype. The loxP sites flanking the *Pax-cherry* cassette were used to remove it by subsequent expression of Cre in the germline. In a second step, the attP was used to reinsert an FRT-flanked fragment comprising the region of *RPS26* deleted in the first step along with a *tubulin-Cherry* fragment. This was achieved by cloning the *RPS26* region and *tubulin Cherry* between the two FRT sites of the pRIV-Pax-Cherry vector, which allowed ΦC31 mediated integration into the attP site of *RPS26[attP-KO]* [61]. In the resulting strain, *RPS26* could be inactivated in a spatially restricted domain (marked by the loss of Cherry expression) with FLP recombinase.

A stop codon readthrough reporter was generated by cloning Firefly luciferase (Fluc) and Nanoluciferase (Nluc) into a pUAS-attP vector (pJFRC81, Addgene #36432). The Fluc coding sequence was amplified from pSGDlucV3.0 (Addgene #119760) and Nluc from pUAS-NanoLuc (Addgene #87696). The stop codon of Fluc was replaced by UGAC and DNA encoding a flexible linker (3XGGGGS). The resulting plasmid, pUAS Fluc-stop-Nluc, was introduced in the germline by site-specific integration at the attP2 docking site on the third chromosome.

The *RPS23[R67K/R67K]* HEK293 cell line was generated using CRISPR/Cas9-mediated homologous directed repair. The sgRNA targeting *RPS23* was cloned into the pSpCas9(BB)-2A-Puro vector (PX459, Addgene #48139) and co-transfected with ssODNs containing the R67K mutation and a silent mutation which generated an EcoR1 site. After puromycin selection, candidate clones were screened by PCR and EcoR1 digestion. Positive clones were confirmed by Sanger sequencing. The PX459 vector was a gift from Feng Zhang [62].

Generation of clones by heat-shock and FLP/FRT-mediated mitotic recombination

The FLP/FRT technique was used to generate mitotic recombination clones [63]. Flies were allowed to lay eggs for 4 h and staged larvae (at the L2-L3 transition) were heat-shocked at 37 °C for 1h. Animals were dissected 72 hours after clone induction and processed for immunostaining.

Generation of RP-heterozygous mutant wing disc compartments

For the generation of imaginal discs with one half *RPS23[R67K/+]* and the other half genetically wild type we first introduced an FRT site proximal to the *RPS23[R67K]* chromosome. The resulting chromosome was then put in *trans* over a chromosome bearing the same FRT site at the homologous position. Expression of FLP recombinase under the control of the *hedgehog* promoter (*hh GAL4, UAS-FLP*) was used to induce mitotic recombination throughout the posterior compartment, leading to the generation of two genetically distinct cell populations: *RPS23[R67K/R67K]*, which are not viable, and *RPS23[+/+]*,

which populated the whole compartment. In the resulting imaginal discs, the anterior compartment remained $RPS23^{R67K/+}$.

For the generation of imaginal discs with one half $RPS26^{KO/+}$ and the other half genetically wild type we took advantage of the fact that the $RPS26[cKO]$ allele is conditional. A FLP transgene was expressed in the posterior half to excise the second exon, along with the *tubulin-Cherry* cassette, from $RPS26[cKO]$ while leaving the wildtype homologous chromosome unchanged. This genetic manipulation thus generated a heterozygous posterior compartment ($RPS26^{KO/+}$) marked by the loss of Cherry fluorescence and a control (wild type) anterior compartment.

Developmental timing

Developmental timing was determined in both wild type and $RPS23^{R67K/+}$ animals with four replicates each. Adult flies were allowed to lay eggs for a period of 4 h. Freshly hatched first instar larvae (L1) were collected and transferred to vials and new pupae were scored every 4 h. The datasets of all replicates were pooled, and the corresponding mean and SD were calculated for each timepoint in Microsoft Excel. Results were represented in a cumulative percentage distribution plot using GraphPad Prism 8.

Translational fidelity assay and quantification

Expression of UAS-Fluc-stop-Nluc was driven ubiquitously with the *tubulin-GAL4* driver. Fluc and Nluc luminescence was assayed with the Nano-Glo Dual-Luciferase Reporter Assay System (NanoDLR, Promega #N1610). Positive controls and experimental animals were processed and assayed in parallel. Larvae were collected, washed in PBS and three larvae per tube were homogenised with a pestle in 500 μl of 1X Passive Lysis Buffer (PLB, Promega #E1941). The tubes were then placed in an orbital nutator for 10 min at 4 °C to complete lysis. Tubes were spun at max speed in a benchtop centrifuge for 3 min and the top fatty layer was discarded. For the Fluc reaction, 80 μl of lysate were transferred into a new tube and mixed with 80 μl of ONE-Glo EX reaction mix. Fluc relative luminescence units (RLU) were measured immediately with the GloMax 20/20 single tube luminometer (Promega #E5311). To assay for Nluc luminescence, 80 μl of the NanoDLR Stop & Glo reaction mix were added and tubes kept in the dark for 10 min to fully quench Fluc activity. Nluc luminescence was then measured with the GloMax 20/20 luminometer. The ratio of Nluc/Fluc RLU served as an estimate of stop codon readthrough. Ratios were normalised to the average of that in wild type control larvae to represent the fold-change (FC). To validate the reporter, early third instar larvae (eL3) were transferred to 50 mm Petri dishes containing 10 ml of food supplemented with 300 μg/ml of G418 (Sigma #G8168). Larvae were allowed to feed during 48 h before being processed for luciferase activity as described above.

Rapamycin treatment

Recently hatched L1 larvae were grown into 50 mm petri dishes with normal food. When larvae reached the early L3 stage, they were transferred into new dishes containing 10 ml of food supplemented with 40 μM of Rapamycin (Sigma #37094) or vehicle and allowed to feed during 48 h before being processed for immunostaining.

Mammalian cell culture

Wild type and $RPS23^{R67K/R67K}$ HEK293 cells were cultured in complete Dulbecco's modified Eagle's medium (DMEM, ThermoFisher #31966021) supplemented with 10% (v/v) Fetal Bovine Serum (FBS, ThermoFisher #A3160402) and 1% (v/v) Pen/Strep (ThermoFisher #15140122) at 37 °C in a humidified chamber with an atmosphere of 5% CO_2.

Antibodies and dyes

The following primary antibodies were used: rat anti-Ci (1:50, DSHB #2A1), mouse anti-Nub (1:50, DSHB #2D4), mouse anti-Wg (1:500, DSHB #4D4), rabbit anti-Dcp1 (1:500, CST #9578), rabbit anti-P-eIF2α (1:100, clone D9G8, CST #3398), mouse anti-Ubiquitin (1:10000, clone FK2, Merck #04-263), rabbit anti-Drosophila p62 [1:2000, kind gift from Tor Erik Rusten [64]], mouse anti-human p62 (1:300, clone 2C11, Novus Biologicals H00008878-M01). Alexa Fluor and Alexa Fluor Plus secondary antibodies raised in goat were obtained from ThermoFisher and used at 1:1000 dilution (#A32731, #A32732, #A32723, #A32727, #A-21247). DAPI was used at final concentration of 0.1 µg/ml (Sigma #D9542).

Immunostaining protocol

Larvae were inverted in ice-cold PBS, fixed in 4% methanol-free formaldehyde (Pierce, ThermoFisher #28906) for 30 minutes and then rinsed in PBS. Inverted larvae were permeabilised in PBS + 0.1% Triton X-100 (PBT× 0.1%) for 30 minutes and blocked for 1 hour in 0.1% PBT× with 2% Normal Goat Serum (ThermoFisher #01-6201) before incubation in a solution of primary antibodies diluted in PBT× 0.1% (without blocking agents or carrier proteins) overnight at 4 °C with gentle rotation. After primary antibody incubation, samples were rinsed 3 × 15 min in PBT× 0.1%. Secondary antibodies and DAPI were diluted together in PBT× 0.1% and incubated with samples at room temperature for 1.5 h in an orbital nutator. After secondary incubation, samples were rinsed 3 × 15 min in PBT× 0.1% followed by a final rinse in PBS. Wing discs were then dissected out of the inverted larvae and mounted in glycerol-PBS mounting medium [40 ml glycerol + 5 ml 10X PBS + 450 µl N-propyl-gallate (50% m/v in ethanol)].

Lysotracker staining

Larvae were inverted in pre-warmed PBS at 25 °C and transferred into a 1.5 ml tube containing pre-warmed PBS. The buffer was then replaced with 1 µM Lysotracker Red DND-99 (ThermoFisher, #L7528) in PBS and the tubes were placed in an orbital nutator for 10 min at room temperature. The larvae were then rinsed 3 × 1 min in PBS to remove residual dye and fixed in 4% methanol-free formaldehyde. After fixation, larvae were rinsed in PBS and discs mounted in mounting medium.

Puromycin incorporation assay

Puromycin incorporation was assayed using the Click-iT Plus OPP Alexa Fluor Protein Synthesis Assay Kits (ThermoFisher #C10456 and #C10457) according to manufacturer instructions with minor modifications, as outlined below. Larvae were inverted in pre-

warmed Schneider's *Drosophila* Medium at 25 °C (Gibco, ThermoFisher #21720024) and transferred into a 1.5 ml tube with pre-warmed Schneider's medium. The medium was then replaced with either 1 μM O-propargyl-puromycin (OPP) in Schneider's medium for 15 min or 20 μM for 30 min with gentle rotation at room temperature. After OPP incorporation, inverted larvae were rinsed in PBS, fixed in 4 % methanol-free formaldehyde and rinsed again in PBS before a permeabilization and blocking step. The Click-iT reaction mix was prepared as per manufacturer instructions and larvae were incubated for 30 min in the dark at room temperature. Samples were finally rinsed in Reaction Rinse Buffer and stained with DAPI. Discs were dissected out and mounted in mounting medium.

Image acquisition and processing

Samples were imaged using a Leica TCS SP5 confocal microscopy and confocal stacks (1 μm step-size) were processed and analysed with FIJI (ImageJ, N.I.H). Images were assembled into figures with Adobe Photoshop CC 2018, 19.0 release. Cartoons were drawn with Adobe Illustrator CC 2018, 22.0.1 release.

Quantification of apoptosis in imaginal discs

Apoptosis was quantified in the wing pouch, marked with anti-Nub staining or recognised by the folds that surround this part of the disc. Confocal planes covering all apoptotic cells (Dcp1 positive) along the apico-basal axis of wing discs (excluding the peripodial membrane) were max-projected with FIJI. The pouch was outlined manually, and its area calculated. To segment the apoptotic cells, a threshold excluding background was applied to generate a binary mask. The resulting regions of interest (ROIs) were used to determine the area covered by apoptotic cells. Apoptosis coverage was calculated as the percentage (%) of the total wing pouch area occupied by apoptotic cells. Graphical representation of all datapoints was made in scatter plots using GraphPad Prism 8. For statistical analysis, a two-tailed unpaired t-test was carried out in Microsoft Excel. ***$P<0.001$

Quantification of HTT aggregates in imaginal discs

The formation of HTT25Q aggregates was quantified in the wing pouch, marked by the fluorescence of HTT25Q-Cerulean, which was expressed under the control of the pouch-specific driver *pdm2-GAL4*. Confocal planes covering all fluorescent signal along the apico-basal axis of wing discs were max-projected with FIJI. The pouch was outlined, and its area measured. To segment HTT25Q aggregates, a threshold excluding background was applied to generate a binary mask and the area covered by aggregates was calculated as the ratio of aggregates area/wing pouch area. The ratios were normalised to the wild type control and represented as the fold-change (FC). All data points were represented in scatter plots using GraphPad Prism 8. For statistical analysis, a two-tailed unpaired t-test was carried out in Microsoft Excel. ***$P<0.001$

## Quantification of p62 bodies in HEK293 cells

The presence of p62 bodies was quantified in wild type and in $RPS23^{R67K/R67K}$ HEK293 cells with anti-p62 staining. Control and experimental cells were fixed and immunostained in parallel, and images were acquired under identical confocal settings. To segment p62

punctae, confocal planes covering all fluorescent signal along the apico-basal axis were max-projected. The background was then subtracted using a 10-pixel radius rolling ball and identical thresholds were subsequently applied to each image to cover p62 bodies. Images were then converted into binary masks, the segmented particles selected as ROIs and the total area covered by p62 bodies measured. For each image, the ratio of p62 bodies area/ number of nuclei was calculated and normalised to the average of the wild type control. The p62 coverage was represented as the fold change (FC) in scatter plots using GraphPad Prism 8. For statistical analysis, a two-tailed unpaired t-test was carried out in Microsoft Excel. **$P<0.01$

Quantification of ubiquitin and p62 punctae in wing imaginal discs

The accumulation of ubiquitin and p62 was quantified in imaginal discs composed of one half heterozygous for the RPS23[R67K] allele and the other half genetically wild type (hence serving as an internal control). To segment ubiquitin and p62 punctae in wing discs (Fig. 2f-i), confocal planes covering all fluorescent signal along the apico-basal axis were max-projected and the same threshold was subsequently applied to all images. Images were then converted into binary masks, the segmented particles selected as ROIs, and the area covered by Ubiquitin or p62 was calculated relative to the area of the mutant or wild type compartment. The Ubiquitin and p62 data were represented in scatter plots as the fold-change (FC) in the mutant compartment versus the wild type compartment. For statistical analysis, a two-tailed unpaired t-test was carried out in Microsoft Excel. **$P<0.01$ and ***$P<0.001$

Proteomic analysis

50 imaginal discs were dissected and lysed in 40μl of extraction buffer containing 1% Triton, 50 mM Tris-HCl pH 7.5, 150 mM NaCl, 2X Halt protease/phosphatase inhibitors (ThermoFisher #78441), 5mM EDTA, 1 mM DTT. Proteins were reduced and alkylated using DTT and Iodoacetamide. The sample volumes were then adjusted to 100μl using LC-MS grade water and subjected to acetone precipitation to remove detergents. Air dried acetone precipitated pellets were resuspended 25μl in 100 mM HEPES, 1M GuaHCl, pH8 in an ultrasonic bath. Endoprotease lysC was added in a 1:50 (enzyme: protein) and incubated at 37 degrees for 3h. The sample was then diluted 2-fold with MilliQ water and trypsin was added in a 1:50 (enzyme: protein) and incubated overnight at 37 degrees. The digests were acidified using TFA and prepared for mass spectrometry analysis using an EvosepOne liquid chromatography system coupled to an Orbitrap Fusion Lumos Mass Spectrometer run in Data Dependent Acquisition mode. Raw data was then processed using MaxQuant v1.6.12.0 specifying iBAQ quantification with further downstream statistical analysis in Perseus 1.4.0.2.
Extended Data
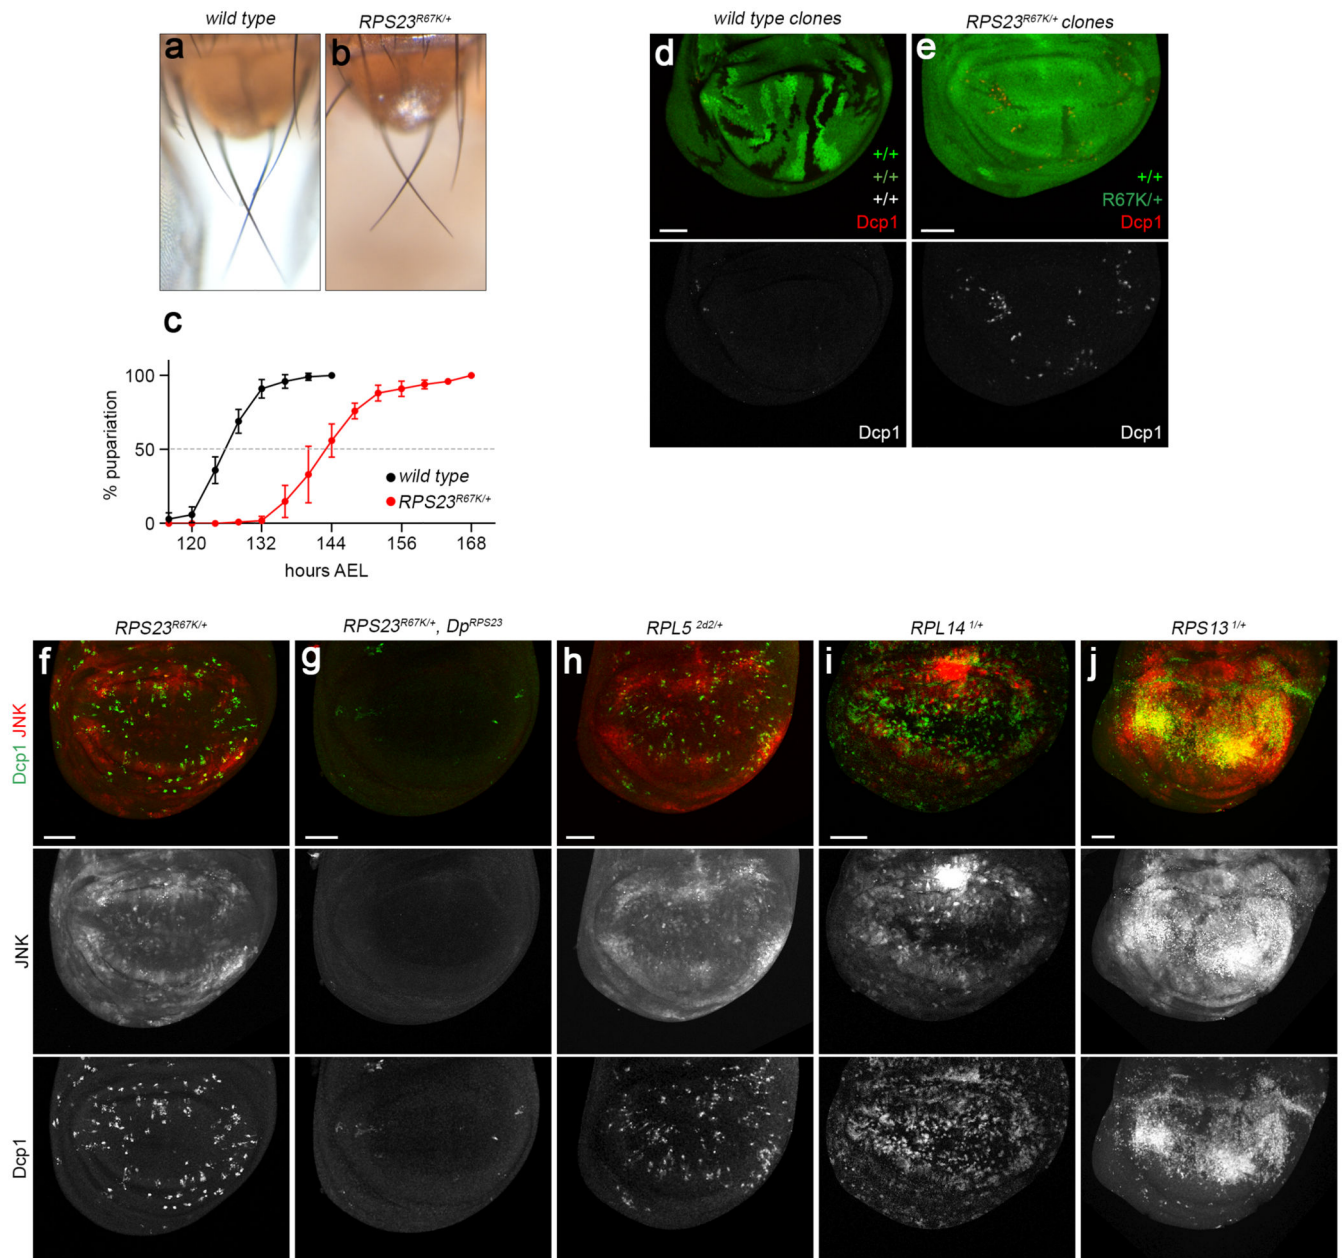

**Extended data figure 1. Phenotypes of Minute heterozygotes**
(**a, b**) Scutellar region of control and $RPS23^{R67K/+}$ flies showing the short-bristle phenotype that characterises *Minute* heterozygotes. (**c**) Cumulative distribution of pupariation time for control (n = 143 larvae) and $RPS23^{R67K/+}$ (n = 134 larvae). Error bars represent standard deviation (**d**) Control mosaic imaginal disc harbouring wildtype clones (2X GFP) and their wild type twin clones (absence of GFP), induced by heat shock-mediated expression of FLP (*hs-FLP*). Note the low number of Dcp1-positive cells (red and grey). (**e**) Mosaic imaginal discs harbouring wild type clones (2X GFP) in a $RPS23^{R67K/+}$ background (1X GFP), also

induced with *hs-FLP*. Here the twin clones ($RPS23^{R67K/R67K}$) are rapidly eliminated and the wild type cells outcompete the $RPS23^{R67K/+}$ cells, which undergo a high rate of apoptosis (Dcp1, red and grey). (**f, g**) JNK signalling (indicated by expression of the TRE-GFP reporter and apoptosis (Dcp1) in $RPS23^{R67K/+}$ are fully supressed by a wild type copy of *RPS23* from a genomic duplication (**g**). (**h-j**) JNK signalling and apoptosis in a panel of heterozygous *Minute* mutants (*RPL5*, *RPL14*, and *RPS13*). Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.

RPS23^{R67K/+}, ci>Xrp1^{RNAi}

Extended data figure 2. Xrp1 is required for activation of apoptosis in *RPS23^{R67K/+}*.
(a) Imaginal disc of a *RPS23^{R67K/+}* larva expressing an RNAi transgene against Xrp1 in the anterior compartment (marked with anti-Ci). The number of Dcp1-positive cells is lower in the anterior than in the posterior compartment where Xrp1 activity is unaffected. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Experiments were repeated independently three times with similar results.
Extended data figure 3. Manipulation of Rheb activity affects OPP incorporation in wild type and *RPS23^{R67K/+}* imaginal discs.

(**a-d**) Wing imaginal discs (*wild type and RPS23^{R67K/+}*, as indicated) overexpressing Rheb or Rheb^{RNAi} in the anterior compartment (left hand side of the disc). The discs were explanted and incubated for a 15 min in 1 μM OPP before staining for puromycilated peptides (grey scale). Rheb overexpression stimulated OPP incorporation in both genotypes, while Rheb^{RNAi} had the opposite effect. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Experiments were repeated independently three times with similar results.
Extended data figure 4. _RPS23_[R67K/+] imaginal discs develop tumours upon inhibition of apoptosis.

(**a-b**) Wing disc from a _RPS23_[R67K/+] larva expressing P35, a baculovirus-derived inhibitor of effector caspases in the pouch (under the control of _rotund-GAL4)_. Note the overgrowth characterised by epithelial folds and ectopic Wingless expression (green), shown in grey scale at higher magnification in **b**. Formation of these tumours shows that RP-deficient cells are not inherently incapable of growth. Tumour formation may be relevant to the increase cancer risk associated with human ribosomopathies as well as to the observation that ribosomal protein genes are frequently deleted in human cancers, often in concert with the loss of TP53[3]. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Experiments were repeated independently three times with similar results.
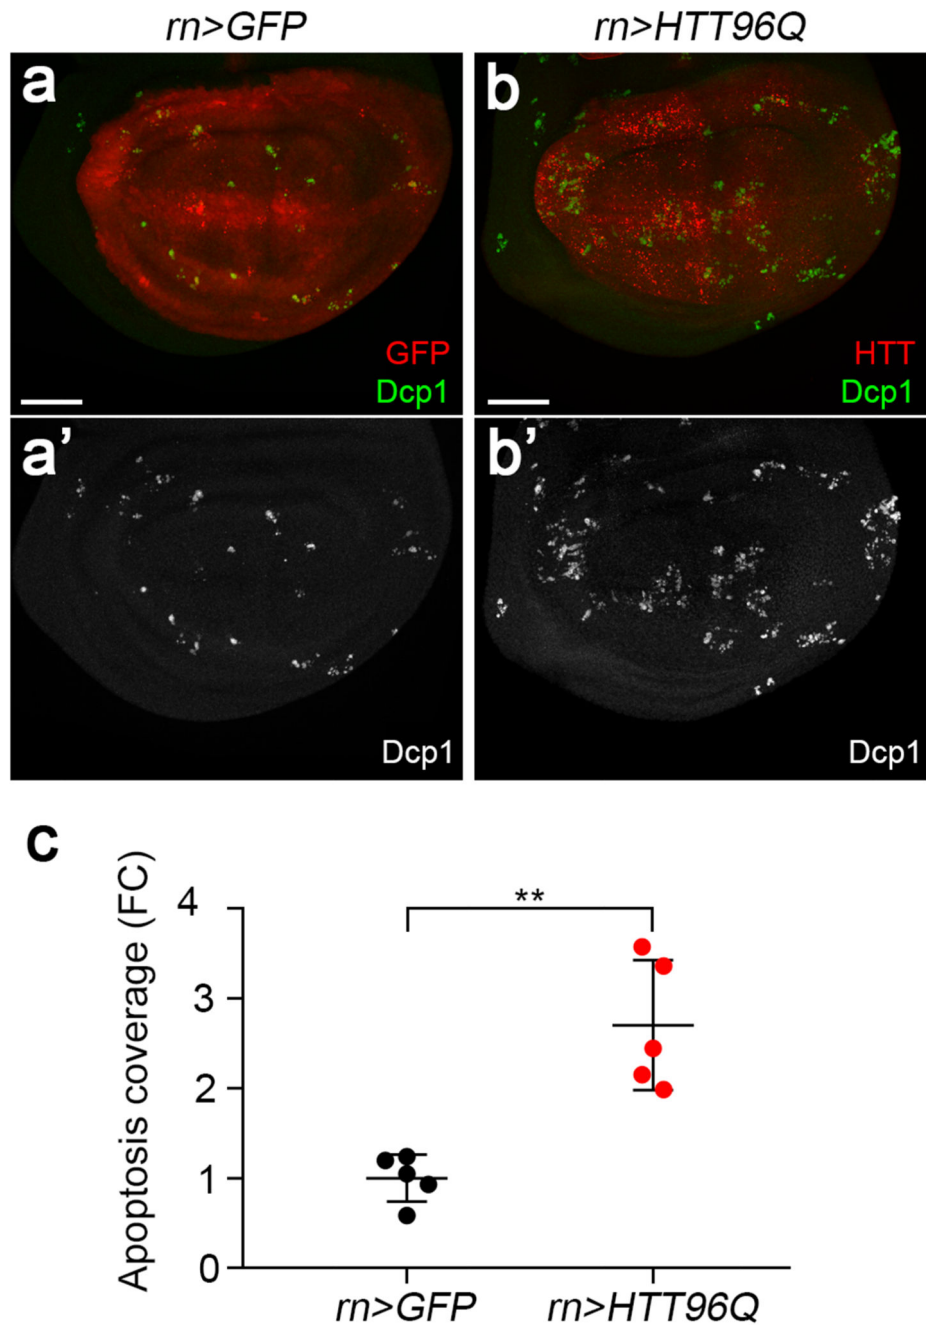

Extended data figure 5. A toxic form of Huntingtin (HTT96Q) triggers apoptosis.
(**a,b**) Expression of HTT96Q throughout the pouch (with *rotund-gal4*) triggers an increased rate of apoptosis relative to that seen with GFP expression, which is expected to be innocuous. (**c**) Quantification of Dcp1 coverage in the two genotypes shown in panels **a** and **b** (n = 5 discs per genotype). Error bars denote standard deviation. For statistical analysis, a two-tailed unpaired t-test was carried out. **P = 4.11E-03. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
Extended data figure 6. Accumulation of p62 and P-eIF2α in *RPS26^{KO/+}*.
(**a, b**) *RPS26^{cKO}* was inactivated (and *tubulin Cherry* deleted) by crossing to *hedgehog-GAL4, UAS-FLP*. In the resulting *RPS26^{KO/+}* posterior compartment, immunoreactivity against p62 and P-eIF2α was higher than in the control anterior compartment. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Experiments were repeated independently three times with similar results.
Extended data figure 7. RP deficiency alters the activity of an autophagy reporter.
(**a**) Cartoon showing progression through autophagy as monitored by the GFP-mCherry-Atg8a reporter. Yellow indicates the simultaneous presence of GFP and Cherry in the phagophore and autophagosome. Autolysosomes only retain the red colour because of the drop in pH, which quenches GFP fluorescence. (**b, c**) Fluorescence from GFP-mCherry-Atg8a, expressed with *tubulin-GAL4* in wild type or *RPS23$^{R67K/+}$*. Single fluorescence channels are also shown in grey. Scale bars represent 50 μm. Genotypes for each figure

panel are available in Supplementary Table 1. Experiments were repeated independently three times with similar results.

a

b
Extended data figure 8. Translation fidelity is unaffected in *RPS23$^{R67K/+}$*.
(**a**) The stop codon readthrough reporter comprises 10X Upstream Activator Sequences (UAS), which confers GAL4 responsiveness, the 5' UTR from Syn21, the coding region of Firefly luciferase (Fluc), a STOP codon (UGAC), a flexible linker, the coding region of Nanoluciferase (Nluc), and the 3'UTR from p10. (**b**) Quantification of the Nluc/Fluc ratio, measured from whole larvae lysates and normalised to that in control larvae. Statistical analysis: 4 replicates for each condition. Error bars denote standard deviation. A two-tailed unpaired t-test was carried out. P>0.05, no significant increase was seen in *RPS23$^{R67K/+}$* larvae. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
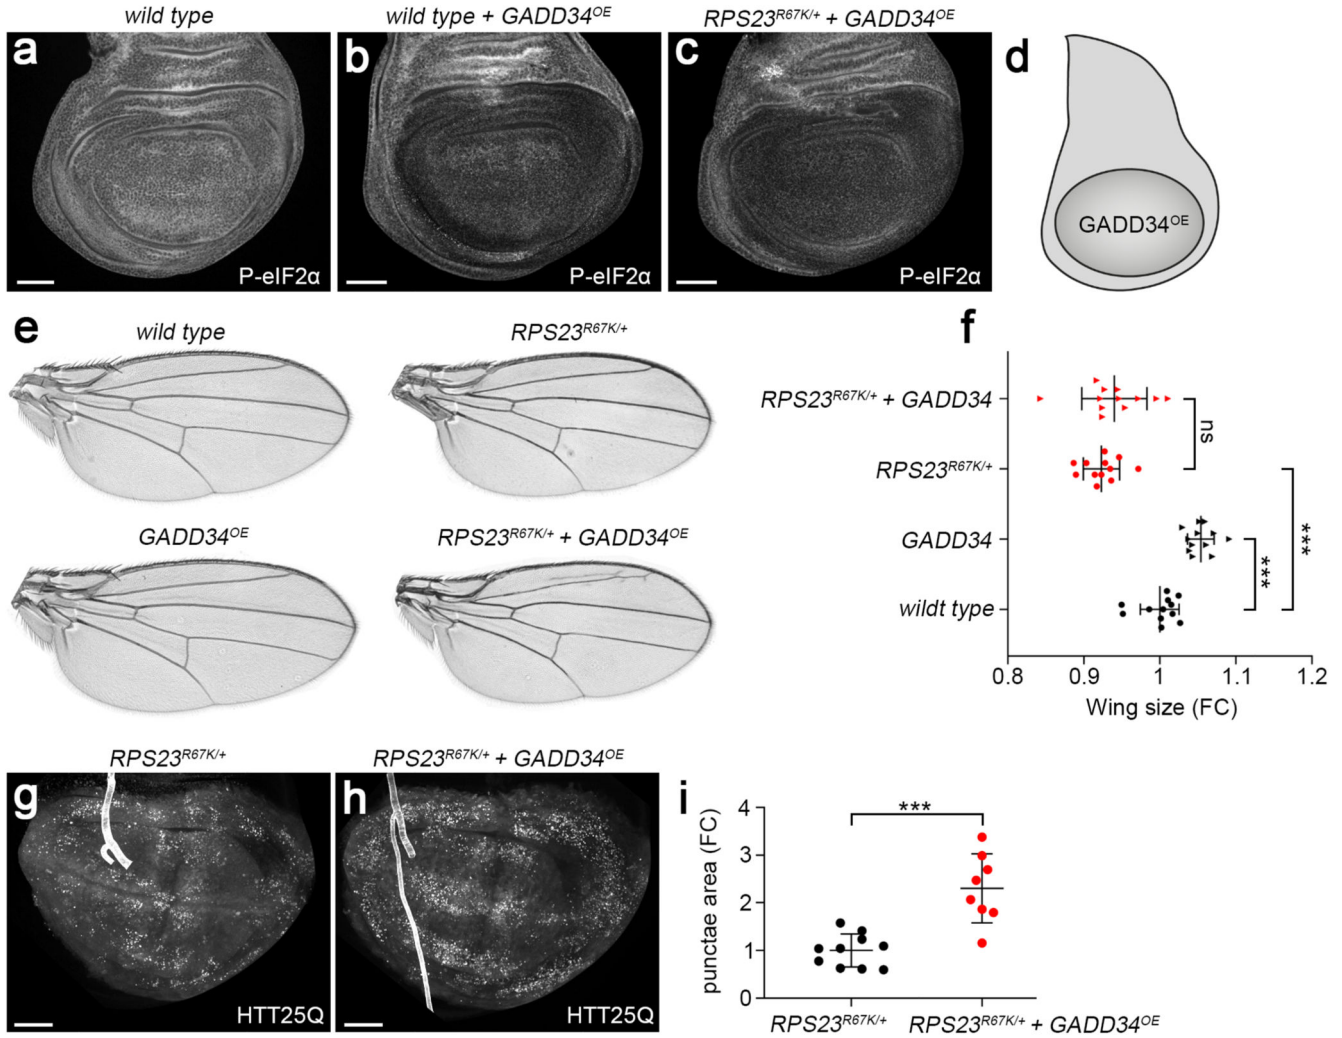

Extended data figure 9. Validating the effect of GADD34 overexpression.
(**a**) P-eIF2α immunoreactivity in a wild type imaginal disc. (**b**) This is reduced by GADD34 overexpression (GADD34^{OE}) driven by *nubbin-GAL4.* (**c**) P-eIF2α immunoreactivity is similarly decreased in *RPS23$^{R67K/+}$* larvae overexpressing GADD34. (**d**) Schematic representation of the domain where GADD34 was overexpressed. (**e**,**f**) GADD34 overexpression causes a mild but significant increase in wing size in otherwise wild type flies but not in *RPS23^{R67K}* heterozygotes. Note that the wing of *RPS23^{R67K}* heterozygotes is smaller than that of wildtype. (**g-i**) GADD34 overexpression exacerbates the formation of HTT25Q punctae in *RPS23^{R67K}* heterozygotes. Statistics: error bars denote standard deviation. In **f**, n = 12 adult wings for each genotype. In **i**, from left to right, n = 10 and 8 discs. A two-tailed unpaired t-test was carried out. P-values in **f**, from top to bottom: 2.48E-01, 1.31E-07 and 7.09E-06. P-value in **i**, 9.65E-04. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
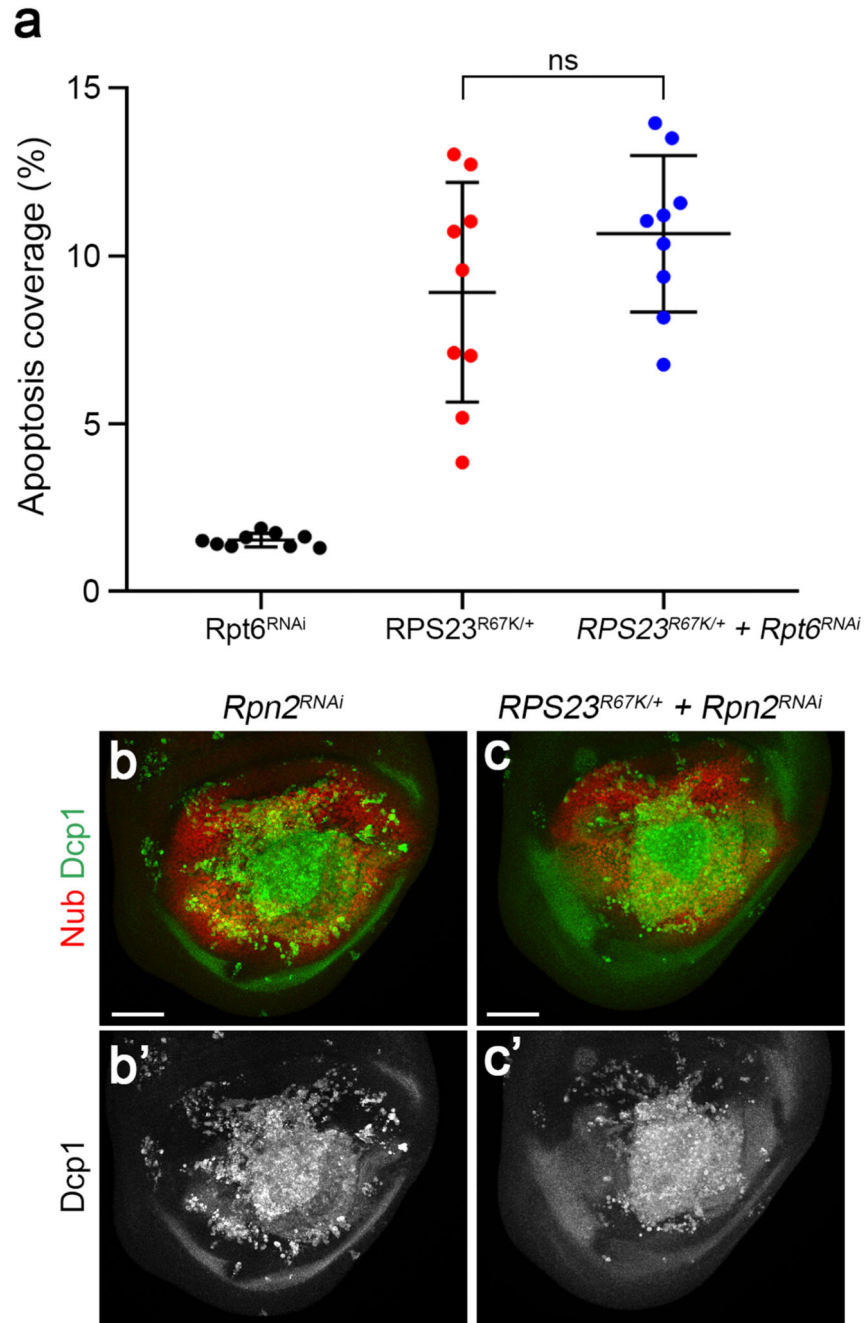

Extended data figure 10. Effect of proteasome inhibition on the rate of apoptosis in RP-deficient tissues.

(**a**) Extent of apoptosis (coverage of Dcp1 immuno-reactivity) in the pouch of discs of genotypes indicated. $Rpt6^{RNAi}$ denotes $rotund$-$gal4$-driven expression of a $Rpt6^{RNAi}$ transgene.. This particular $Rpt6^{RNAi}$ transgene had only a minor effect on apoptosis in wildtype tissue. Expression of this RNAi transgene did not enhance the rate of apoptosis in $RPS23^{R67K}$ heterozygotes. (**b**) The effect of stronger proteasome knockdown (with $Rpn2^{RNAi}$) on the rate of apoptosis in RP-deficient tissue could not be assessed because it

triggered extensive apoptosis in otherwise wild type imaginal discs. Statistics: error bars denote standard deviation. n = 9 discs for each genotype. A two-tailed unpaired t-test was carried out. P>0.05, no significant difference was seen. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.

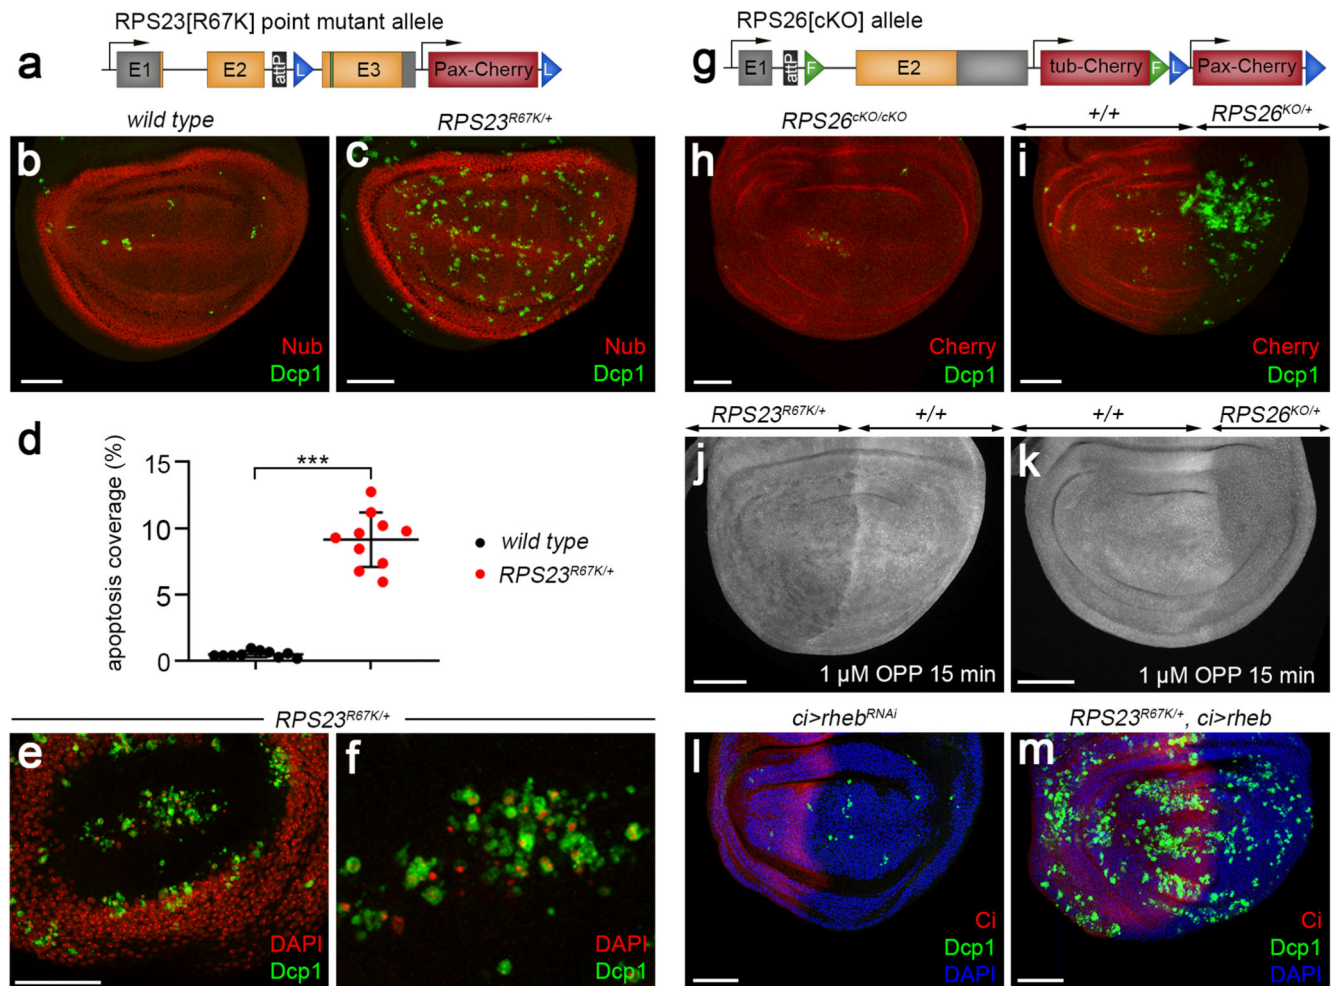

Figure 1. Apoptosis and depressed protein synthesis in RP-deficient tissue.
(**a**) Diagram of the *RPS23*^{R67K} allele showing the 5' and 3' UTRs (grey), the coding exons (orange), attP (black), loxP (blue) and the *Pax-Cherry* selection cassette (red). The vertical green bar indicates the location of the R67K substitution. (**b,c**) Wing imaginal discs from wild type and *RPS23*^{R67K/+} larvae labelled with anti-Nub (red) to highlight the pouch and anti-Dcp1 (green) to mark apoptotic cells. (**d**) Apoptotic coverage (% surface area) in wild type (black dots) and *RPS23*^{R67K/+} imaginal discs (red dots). (**e, f**) Accumulation of pyknotic nuclei in a *RPS23*^{R67K} heterozygous disc. (**g**) Diagram of the conditional RPS26 allele (*RPS26*^{cKO}; colour code as in panel a. The FRT sites used for gene inactivation are depicted in green). (**h**) Homozygous *RPS26*^{cKO} imaginal disc (wild type for *RPS26* activity) showing expression of the *tubulin-Cherry* cassette and low-level apoptosis (Dcp1 immunoreactivity). (**i**) *RPS26*^{cKO/+} imaginal disc expressing FLP under the control of *hedgehog-GAL4*. The posterior compartment is hence heterozygous for the *RPS26* mutation, as confirmed by the lack of Cherry expression. Note the increased number of apoptotic figures. (**j, k**) Wing imaginal discs with one half heterozygous mutant for *RPS23*^{R67K} or *RPS26*^{KO} and the other half genetically wild type, stained to visualise puromycilated peptides following a 15 min incubation in 1 μM of OPP. In both cases,

incorporation is depressed in the mutant compartment. (**l, m**) Dcp1 immunoreactivity in wild type wing imaginal disc expressing Rheb^{RNAi} in the anterior compartment or *RPS23$^{R67K/+}$* wing imaginal disc overexpressing Rheb in the anterior compartment (left hand side, marked with anti-Ci). Statistics in **d**: n = 10 discs per genotype. Error bars denote standard deviation. A two-tailed unpaired t-test was carried out. ***P = 2.87E-07. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
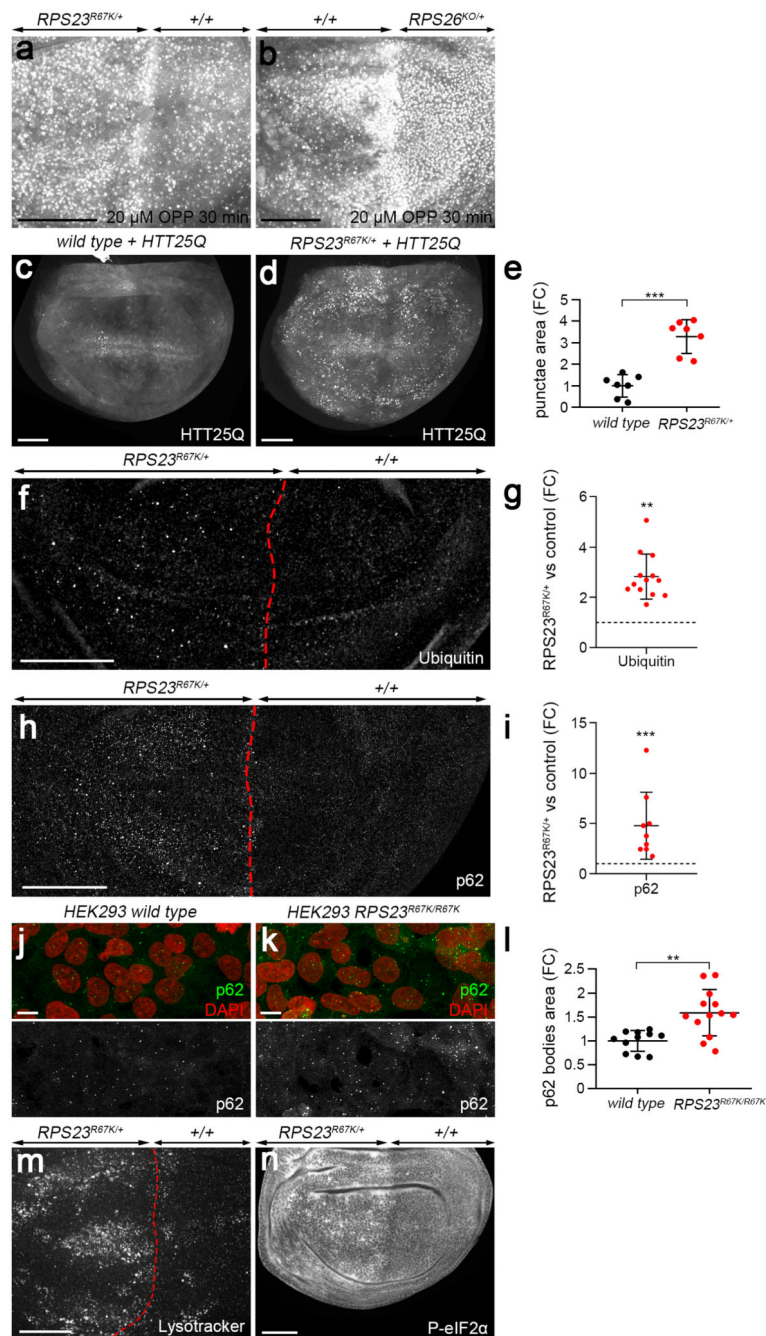

Figure 2. Hallmarks of proteotoxic stress in RP-deficient cells.
(**a, b**) Wing discs with one half $RPS23^{R67K/+}$ or $RPS26^{KO/+}$, labelled to visualise puromycilated peptides following a 30 min incubation in 20 μM of OPP. (**c, d**) Wing primordia from wild type or $RPS23^{R67K/+}$ larvae expressing HTT25Q-Cerulean throughout the pouch (under the control of *pdm2-GAL4*). (**e**) Quantification of HTT25Q punctae in $RPS23^{R67K/+}$ tissue (red dots, genotype as in panel **d,** n = 7 discs), expressed as a fold change (FC) in surface area coverage relative to that in otherwise wild type tissue (black dots, genotype as in panel **c,** n = 7 discs). (**f,g**) Anti-ubiquitin staining of a mosaic wing disc

with the anterior half $RPS23^{R67K/+}$. Increased punctae staining in the anterior compartment expressed as a ratio with the posterior signal (n = 13 discs). (**h,i**) Anti-p62 staining of the same genotype as in panel **f** and quantified as for panel **g** (n = 9 discs). (**j, k**) Wild type or $RPS23^{R67K/R67K}$ HEK293 cells stained with anti-p62 (green) and DAPI (red). (**l**) Coverage of p62 immunoreactivity in $RPS23^{R67K/R67K}$ (n = 13 images) relative to that in wild type HEK293 cells (n = 11 images). (**m**) Lysotracker staining in a wing disc with one half $RPS23^{R67K/+}$. (**n**) P-eIF2α immunoreactivity in a wing disc with one half $RPS23^{R67K/+}$. Statistics: all error bars denote standard deviation. For panels **e**, **g**, **i** and **l**, a two-tailed unpaired t-test was carried out. P-values in **e,** ***P = 5.81E-05; **g,** **P = 1.08E-03; **i**, ***P = 1.96E-04; **l**, **P = 1.07E-03. Scale bars: 50 μm in panels **a-h** and **m, n**, and 10 μm in panels **j, k**. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
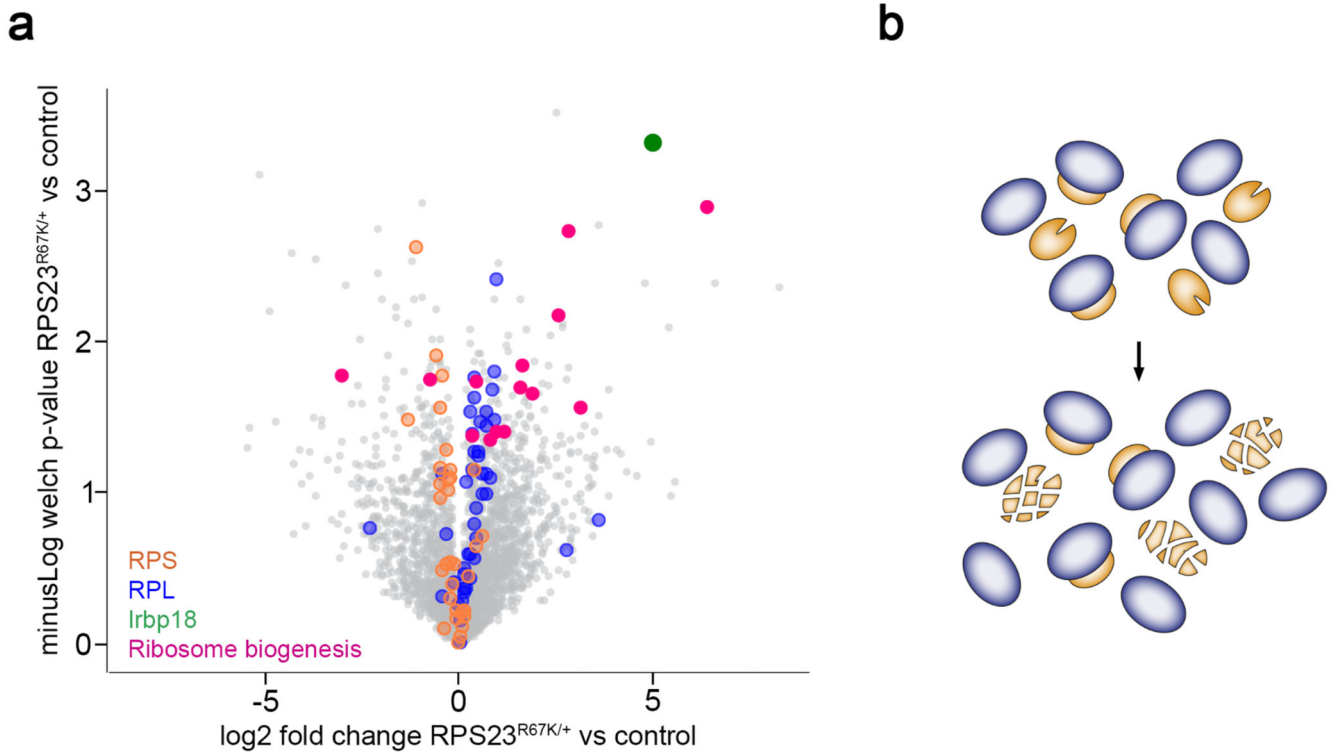

**Figure 3. Proteomic analysis of RP-deficient imaginal discs.**
(a) Volcano plot displaying changes in the abundance of proteins in $RPS23^{R67K/+}$ relative to wild type. The green dot highlights IRBP18, while red dots show all the proteins annotated as being involved in ribosome biogenesis (as determined from flybase.org and/or Uniprot) that are changed in a statistically significant manner. The plot also displays the changes in the abundance of ribosomal proteins in $RPS23^{R67K/+}$ relative to wild type. On average, proteins of the small subunit (RPS, orange circles) are underrepresented while those of the large subunit (RPL, blue circles) are enriched in mutant discs. **(b)** Differential effect of RP deficiency on the abundance of small (orange) and large (blue) subunit proteins. Since only half the complement of functional RPS23 is produced in the $RPS23^{R67K}$ heterozygotes, a large number of small subunit proteins are orphaned and must be disposed of. By contrast, all the large subunit proteins produced by the cell can assemble in complete subunits. Coloured proteins highlighted in **a** are listed in Supplementary Table 2.
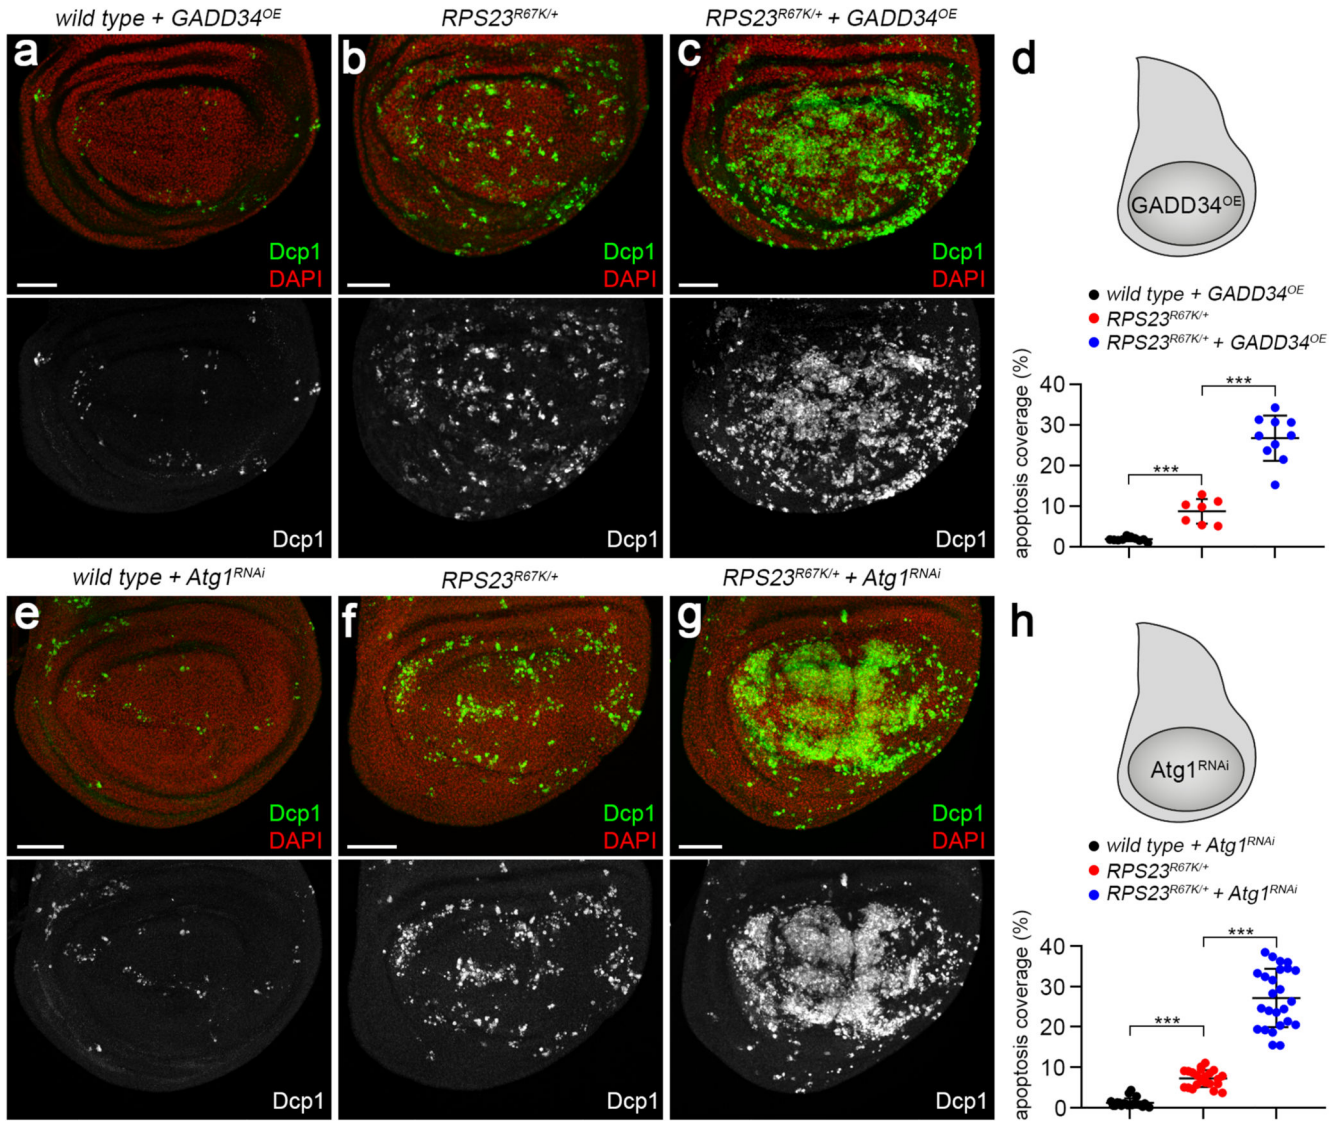

Figure 4. The ISR and autophagy limit tissue damage caused by RP-deficiency.
(**a**) Relatively low number of apoptotic figures (Dcp1, green) in imaginal discs that overexpress GADD34 throughout the wing pouch (with *nubbin-GAL4*). (**b,c**) The rate of apoptosis in heterozygous for $RPS23^{R67K}$ is markedly enhanced upon GADD34 overexpression. (**d**) Quantification of apoptosis coverage (as in Fig.1d) in the three genotypes illustrated in panels **a-c**. (**e**) Relatively low number of apoptotic figures (Dcp1, green) in imaginal discs expressing an $Atg1^{RNAi}$ transgene throughout the wing pouch (with *rotund-GAL4*). (**f,g**) The rate of apoptosis in heterozygous for $RPS23^{R67K}$ is markedly enhanced upon $Atg1^{RNAi}$ expression. (**h**) Quantification of apoptosis coverage in the three genotypes of panels **e-g**. Statistics: in panel **d**, from left to right, n = 10, 7 and 10 discs. In panel **h**, from left to right, n = 21, 22 and 25 discs. All error bars denote standard deviation. A two-tailed unpaired t-test was carried out. P-values, from left to right in **d**: ***P = 9.43E-07, ***P = 5.36E-07 and in **h**, ***P = 2.52E-13, ***P = 1.35E-13. Scale bars

represent 50 µm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
Figure 5. Inhibition of TOR signalling reduces the accumulation of aggregates and apoptosis in RP-deficient cells.

(**a**) Wholly heterozygous $RPS23^{R67K/+}$ disc expressing $Rheb^{RNAi}$ in the anterior compartment (with ci-$GAL4$). The preparation was stained with anti-Ci to mark the domain of expression and anti-Dcp1 for apoptotic figures (**b**) Imaginal discs of the same genotype stained with anti-p62, also shown at higher magnification in **b'**. (**c, d**). Discs from $RPS23^{R67K/+}$ larvae fed for 48 h with vehicle or rapamycin. (**e**) Apoptotic coverage (%) in $RPS23^{R67K/+}$ imaginal discs from larvae fed with vehicle (black dots) of rapamycin (red

dots). n = 29 discs for each condition. Error bars denote standard deviation. For statistical analysis, a two-tailed unpaired t-test was carried out. ***P = 1.41E-11. Scale bars represent 50 μm. Genotypes for each figure panel are available in Supplementary Table 1. Source data is available for this figure.
