Abstract

Background: The important role that the immune system plays in malignant diseases is well known. The action of interleukin-7 (IL-7) as a cytokine has been observed in many cellular processes, both in normal cells of the immune system and in some cancer cells. The aim of this study has been to explore whether there is any elevation of interleukin-7 serum levels in early invasive breast cancer (EIBC) patients in comparison with healthy controls. In addition, the correlation between the IL-7 serum level and the histopathological characteristics of the tumor has been evaluated.

Methods: This cross-sectional, observational, and analytical study included 213 consecutive patients with EIBC (113 from Croatia and 100 from Kosovo) and 62 healthy participants as the control group (30 from Croatia and 32 from Kosovo). Blood samples have been taken from patients confirmed with breast cancer (BC) by biopsy, prior to surgical intervention and other oncological treatments, as well as from healthy participants. A serum IL-7 level has been measured, using the “Sandwich” ELISA Immunoenzyme test. In addition, after the surgical intervention, histopathological specimen examinations and immunohistochemistry have been performed and analyzed. The differences in the distribution of the numerical variables have been analyzed with the Mann–Whitney *U* test and Kruskal–Wallis ANOVA test. Correlations have been tested with Pearson coefficients. A *P*-value < 0.05 has been accepted as statistically significant.

Results: The serum level of IL-7 in EIBC patients was significantly higher than in control cases (*P* 0.001). Patients with invasive lobular carcinoma (ILC) seem to have a lower IL-7 serum level compared to other histological subtypes, and the difference has been significant (*P* = 0.043). There has been no correlation between IL-7 serum level and histopathological characteristics of the tumor, with neither age nor menopausal status of the patients.

Conclusions: Noting the significant increase in the IL-7 serum level in the EIBC patients as compared to the healthy control group, the use of IL-7 as a potential diagnostic indicator for BC, as well as in the follow-up of the patients after treatment, can be assumed. The lack of correlation with tumor size, lymph node metastasis, and all other histopathological characteristics of the tumor questions its use as a prognostic indicator.

Introduction

BC is a common disease worldwide with an increasing incidence every year (2,261,419 new cases for the year 2020), and it is responsible for thousands of deaths

annually (684,996 for the year 2020) [1]. An early and accurate diagnosis is a prerequisite to effective treatment and the survival of the patient. Tumor markers play an important role in clinical practice for screening, disease staging, prognosis, and evaluation of treatment effectiveness in some types of malignancies. Although there are tumor markers such as CEA and CA15-3, which are in use for the follow-up of metastatic BC patients, the investigation of an ideal tumor marker is continuing.

The human body's immune system plays an important role in malignant diseases, first identifying malignant cells and then fighting them. In the early stages of tumor progression, immune cells such as natural killer (NK) and CD8⁺T cells identify and destroy most of the cancer cells [2]. Much research has already been done on different cytokines in order to evaluate their role in the development of various tumors. Recently, the possibility of using different cytokines for the treatment of tumors has been considered [3, 4].

IL-7 is a cytokine of particular importance to the immune system. It supports the development of lymphocytes in the thymus and the organogenesis of the lymph nodes, and it ensures the maintenance of activated T cells in the secondary lymphoid organs [5, 6]. Non-hematopoietic cells that produce IL-7 include fibroblastic cells in the bone marrow and lymphoid organs; epithelial cells in the thymus, prostate, and intestine [7–9]; and keratinocytes in the skin [10]. The production of IL-7 by dendritic cells of the immune system has also been observed [11]. On the other hand, evidence shows that IL-7 can be produced by the stroma of tumor cells [12]. Under physiological conditions in the human body, IL-7 is found in very limited amounts, while the stromal cells produce IL-7 in approximately constant amounts, unaffected by external stimuli [13]. An increase in circulating IL-7 levels has been observed in diseases associated with lymphopenia, such as HIV infections, idiopathic CD4⁺T lymphopenia, and autoimmune diseases [14]. IL-7 acts through the IL-7 receptor (IL-7R), which consists of two chains: Alfa (α) and Gamma (γ). The γ chain is found in all types of hematopoietic cells, while the α chain is mainly expressed in lymphocytes, enabling the development of T and B lymphocytes, respectively, naive and memory T cells [15]. IL-7 action is realized through two main signaling pathways: Jak-Stat and PI3K-Akt [6] (Fig. 1). Through these pathways, they have an impact on the development, survival, proliferation, differentiation, and maturity of immune cells such as T-lymphocytes, B-lymphocytes, and natural killer cells [16]. Some evidence suggests that IL-7 overexpression influences the development and progression of a variety of tumors. Furthermore, IL-7 messenger RNA (mRNA) has been found in many types of tumors, such as renal, colorectal, and

central nervous system (CNS) [17]. IL-7 receptor (IL-7R) mRNA has been seen in a variety of tumor cells, including breast, colon, lung, renal, and CNS [18]. It is now known that IL-7 induces the proliferation of a variety of cancers, such as leukemia and lymphomas [17].

The increased aggressiveness and metastasis in carcinomas, including BC, is associated with epithelial-mesenchymal transition (EMT) as it allows cells to invade surrounding tissues and through the bloodstream to enable the establishment of metastasis. Shreds of evidence show that the PI3K/Akt signaling pathway is implicated in EMT [19, 20]. In addition, overexpression of Akt has been seen frequently in human cancers and is related to tumor metastasis [21]. The results of a previous study show that the IL-7 δ 5 variant supports BC cell proliferation as well as cell cycle progression through the activation of the PI3K/Akt pathway [17]. On the other hand, evidence has shown that the administration of IL-7/IL-7R α -Fc inhibits tumor growth and prolongs survival in lung cancer by inducing afferent and efferent antitumor responses [22]. Furthermore, cytotoxic T lymphocytes reduce pulmonary metastatic sarcoma in mice when stimulated by IL-7 [23]. The possibility of different reactions of IL-7 in different tumor models was described in the previous study [13]. These contradictory findings indicate that more research is needed to determine whether IL-7 functions as a promoter or inhibitor of tumor growth, but they also highlight IL-7's association with tumor development. However, there is a lack of information regarding the correlation between IL-7 serum levels and the histopathological characteristics of BC or the prognosis of the disease.

Thus, the aim of this study has been to observe if there is any elevation in the IL-7 serum level in the EIBC patients compared to the healthy control group. In addition, the correlation between the IL-7 serum level and tumor size, histological type, histological grade, lymphovascular invasion (LVI) and perineural invasion (PNI), metastatic lymph nodes, and molecular markers such as estrogen receptor (ER), progesterone receptor (PR), amplification of Her-2/neu, Ki-67 proliferation index, molecular surrogate subtypes, age, and menopausal status has been evaluated.

The data from this study will contribute to the discussion about the role of IL-7 in the development of BC, in particular, to evaluate the possibility of using IL-7 as a tumor biomarker and prognostic indicator in BC.

Methods

This dual-center, cross-sectional, observational, and analytical study has been undertaken in the Clinic of Oncology, University Hospital Center Zagreb, Croatia, and the Department of Thoracic Surgery in the University

Fig. 1 IL-7 induced intracellular signaling pathways. The non-hematopoietic cell-derived cytokine IL-7 has to combine with the IL-7R on the cell membrane to realize its biological activity. IL-7R complex is a transmembrane heterodimer consisting of two subunits, the ligand-binding IL-7 receptor α chain and the common signal-transducing γ chain (γ chain), which is shared by IL-7R, IL-2R, IL-4R, IL-9R, IL-15R, and IL-21R. JAK/STAT, PI3K-Akt, and MAPK signaling pathways are involved and have specific roles in IL-7-mediated functions. Upon IL-7 binding to its receptor, IL-7Rα, the α and γc subunits dimerize. This induces intracellular, non-receptor tyrosine kinases, Janus kinases (JAK) 1 and 3, to activate and mediate the IL-7 signaling transduction. To this end, the transcription factor Miz1 (Myc-interacting zinc finger protein 1) recruits JAK1 to IL-7Rα. This induces phosphorylation of JAK1 and JAK3, which in turn triggers STAT5 phosphorylation with subsequent dimerization to regulate gene expression, i.e., stimulate anti-apoptotic gene expression and inhibit pro-apoptotic gene expression. On the other hand, JAK1 and JAK3 phosphorylation leads to the activation of MAPK and PI3K-Akt signaling pathway as presented in the figure

Clinical Center of Kosovo in Prishtina, Kosovo, from June 2018 until December 2019. In order to determine the IL-7 serum level, blood samples (10 ml of venous blood) have been taken from 213 EIBC patients, of whom 100 from Kosovo University Hospital and 113 from Croatian University Hospital, prior to surgery and other oncological treatments such as chemotherapy, radiotherapy,

endocrine therapy, or target therapy. On the other hand, the blood samples (10 ml of venous blood) were also taken also from the other 62 healthy participants, who composed the control group, of whom 32 were from Kosovo and the other 30 from Croatia. Blood samples categorized in tubes have been identifiable only by the numbers attributed to participants and have been stored

frozen at temperatures of -20°C , in order to conduct the analysis later.

Patients have been selected as consecutive among women, aged 20–70 who are confirmed to have BC, by biopsy, operable, and without distant metastases. Patients with pathological conditions, such as acute and/or chronic inflammatory diseases, rheumatoid disease, and other malignancies occurring simultaneously; patients receiving immune-modulatory therapy; patients previously treated by surgery, chemotherapy, radiotherapy, target therapy, or endocrine therapy; and patients with dementia, or any other psychological disorders unable to willingly participate in the study, have been excluded. The control group has been composed of women aged 20–70, without breast tumors confirmed by ultrasound or mammography in the last 3 months, or any other confirmed malignancies, without any acute or chronic inflammatory disease, as well as those not receiving immune-modulatory therapy.

In this study, the IL-7 serum level has been measured using the “Sandwich” ELISA Immunoenzyme test, human IL-7 antibody, and Platinum ELISA using research tools from eBioscience Inc., located in San Diego, CA, USA. After the surgery (partial or modified radical mastectomy) with or without axillary lymph node dissection or sentinel lymph node biopsy (SLNB), the histopathological specimen examinations have been performed according to routine practice, and the histopathological and immunohistochemical features have been evaluated. Cancer staging has been conducted according to tumor node metastasis (TNM)-classification by the American Joint Committee on Cancer Classification (AJCC) [24]. The patients have been classified in accordance to their pathological characteristics, including tumor size, histological types, histological grade, LVI and PNI, metastatic lymph nodes, and molecular markers such as ER, PR, amplification of Her-2/neu, Ki-67 proliferation index, and molecular surrogate subtypes according to the St Gallen consensus criteria [25]. The data on age and menopausal status has been obtained from the patients as well.

IL-7 serum levels have been initially determined in all the study participants, including patients and the control group. Then, it was evaluated if there had been any difference in IL-7 serum levels between EIBC patients and the control group. After that, appropriate analyses have been done to see if there is any correlation between the IL-7 serum level of the patients and the histopathological characteristics of the tumor, as well as age and menopausal status. In addition, the potential difference in IL-7 serum levels between patients coming from Croatia and Kosovo has been evaluated.

After checking for normality of distribution, numerical variables have been presented as median and

interquartile ranges. The differences in the distribution of the numerical variables have been analyzed with the Mann–Whitney U test and Kruskal–Wallis ANOVA test. Associations between numerical variables have been analyzed as Spearman rank correlation coefficients. Analyses have been performed with the statistical software SPSS-22.0. A P -value < 0.05 was considered statistically significant. The diagnostic accuracy and the optimal cut-point value for the IL-7 level between two groups have been obtained based on the value of the area under the ROC curve.

Results

Characteristics of all subject variables considered in the two groups, Kosovo and Croatia, are shown in Table 1. The two groups of participants were balanced in terms of the clinical and pathological features of the tumors at the time of the study.

We examined the contribution of IL-7 to early invasive breast cancer. To this end, we analyzed serum levels of IL-7. The IL-7 serum level in EIBC patients was significantly higher than I control cases ($P < 0.001$) (Table 2).

The diagnostic accuracy of a biomarker is a crucial factor. Accordingly, ROC curve analysis has been applied to analyze the diagnostic accuracy of measurements and optimal cut-point values for IL-7 level between verified EIBC and control groups (Figs. 2 and 3).

Regarding the EIBC patients, there have been no correlations between IL-7 serum level and tumor size, age, and Ki-67 (%) (Spearman's $R = 0.5$, $P = 0.4$; Spearman's $R = 0.5$, $P = 0.6$; and Spearman's $R = 0.3$, $P = 0.7$, respectively) (Table 3).

Patients with invasive lobular carcinoma (ILC) seem to have a lower IL-7 serum level as compared to other histological subtypes, and the difference is significant ($P = 0.043$). There have been no significant differences in IL-7 serum levels between different stages of the disease, molecular surrogate subtypes, and histological grades. Immunohistochemical expression or absence of molecular markers, such as PR, ER, amplification of Her-2/neu receptor, and proliferation index as measured by Ki-67, as well as LVI and PNI, have not been correlated with IL-7 serum level (Table 4).

There is no differentiation in the IL-7 serum level between premenopausal and postmenopausal patients, nor between patients coming from Croatia and Kosovo (Table 5).

Discussion

A significantly higher IL-7 serum level in EIBC patients as compared to healthy control cases ($P < 0.001$) has been noticed. On the other hand, no link has been found between IL-7 serum levels and tumor size, lymph

node metastasis, or tumor progression from well to poorly differentiated. The higher IL-7 serum level in BC patients can be explained by the production of different cytokines, including IL-7, by cancer cells [24], but the discontinuing increase of IL-7 serum levels during tumor growth and disease progression is controversial. Another reason for the increase of IL-7 serum levels at the start of tumor growth can be the counteraction of the immune system to the tumor, producing various cytokines, among them IL-7. However, as the tumor progresses in growth, metastasis in lymph nodes, or passes from well to poorly differentiated, the immune parameters fail and are replaced by other inflammatory cytokines, which support the tumor's growth and progression [26]. It is known that the immune system has a key role in a mechanism of preventing the occurrence of cancer, but the immunity fails to strong defense mechanisms developed by the tumor [27–30]. In the tumor microenvironment, immune cells that are tolerant

Fig. 3 The ROC curve analysis of patients with high IL-7 values (≥ 99 pg/ml). IL-7 level 99 showed 88.9% sensitivity and 90.9% specificity for carcinoma. AUC was 0.942 (95% CI 0.819–0.991) at a cut-off value of 41.8 pg/ml

Table 3 Correlation of the tumor size, age, and involved lymph node numbers with IL-7 serum levels

	Spearman's coefficient	P value
Tumor size (mm)/IL-7	0.057	$P=0.4$
Age/IL-7	0.024	$P=0.6$
Ki-67/IL-7	0.028	$P=0.7$

toward tumors, such as exhausted cytotoxic T lymphocytes, macrophages, and T helper cell type 2, can be found, as well as more myeloid-derived suppression cells (MDCS) and T regulatory cells (Treg), responsible for inhibition of effector immune responses [31, 32]. Cancer patients frequently have low T cell counts and, as a result, an immunosuppressive state [33]. Because IL-7 is responsible for the development, growth, and maturation of T lymphocytes [6], low level of T lymphocytes in patients with malignant diseases may be one reason for the increase in circulating IL-7 levels. The increase of the IL-7 serum level in the BC patients in this study does not correspond with the Iranian study, in which no elevation of the IL-7 serum level in the BC patients has been noticed. Moreover, their results show a higher level of IL-7 in the control group [12]. Furthermore, in the Iranian study, a higher level of IL-7 was seen in the serum of well-differentiated BC patients compared to patients with poor differentiation, while in our study there was no difference in the IL-7 serum level between patients with poor and well-differentiated tumors. The previous study has shown that the impact of the IL-7 δ 5 variant through the activation of Akt has a critical role in

cell proliferation, apoptosis, angiogenesis, and metastasis [17], but in our study, there is no correlation between IL-7 serum level and lymph node metastasis, LVI, or PNI, and neither with tumor size has been noticed. Interestingly, a lower value of IL-7 has been observed in the serum of patients with ILC compared to patients with invasive ductal carcinoma (IDC) and other histological subtypes, and the difference has been significant ($P=0.043$). The differences are already evident both histologically and clinically between the two main subtypes of BC, ILC, and IDC, which account for about 95% of all subtypes. Recent studies have also described marked differences in genomic levels between these two subtypes, while genetic level studies are still insufficient [34–36]. Given these differences, it can be probably assumed that the immune system's response may be different in these two subtypes, specifically the production of different cytokines, in this case IL-7. Determining the risk factors that are associated with disease progression and metastasis is of great importance in treatment planning as well as in follow-up after treatment. Different surrogate subtypes of BC have different courses of the disease. The study done by Anwar et al. [37] found that patients with luminal A-like had better disease-free and overall survival as well as bone metastasis, while patients with non-luminal triple negative BC have a tendency to spread in the lungs and generally have a poor prognosis. But, in our study, there was no difference in IL-7 serum level between several molecular surrogate subtypes and in overexpression or not of molecular markers such as ER, PR, and Her-2/neu. No differentiation has been found in IL-7 serum levels between patients regarding age, as well as between patients coming from Croatia and Kosovo.

Menopause is not a factor that causes BC, but there are several risk factors associated with it. The longer exposure to estrogen lasts, the greater the chance of developing BC. In a previous study [38], there were several biological and clinical-pathological differences between premenopausal and postmenopausal BC patients. There was more pronounced heterogeneity and aggressiveness of the disease in the premenopausal group, with a higher rate of lymph node involvement and, as a result, a higher stage of the disease [38]. Molecular markers such as ER, PR, and Her2/neu, which also serve as prognostic factors, are distributed differently in premenopausal and postmenopausal BC patients, with a tendency for overexpression of the triple-negative cases in premenopausal ones [39]. Also, the rate of the cell's poor differentiation is higher in premenopausal patients. Based on these data, BC tends to be more aggressive and with a worse prognosis in premenopausal women. However, no difference has been observed in the IL-7 serum level between premenopausal and postmenopausal patients.

Table 4 The distribution of the IL-7 serum level according to the tumor characteristics

Grouping variables	Categories of grouping variables (n)	IL-7 Median (25–75%)	P value
Histological subtype	IDC (NST) (165)	65.25 (29.4–166.0)	Kruskal–Wallis ANOVA test value $H(2.0) = 6.30$; $P = 0.043$

Tumor markers have an important and ever-increasing role in all aspects of malignant disease care. The detection of a tumor marker can be done in tissue or in various body fluids, including serum, pleural fluid, or ascites. Clinical use may be done for screening or early detection,

completion of diagnosis, determination of prognosis, monitoring of the effectiveness of therapy, and follow-up of disease and recurrence. As tumor markers, there can be different substances: surface antigens, different cytoplasmic proteins, hormones, enzymes, different oncogenes, and their products. Nowadays, when personalized treatment is becoming more and more important, the definition of genetic biomarkers has a special importance in the treatment of BC. The TNM staging system has flaws, so in the 8th edition of the AJCC, ER, and PR expression, as well as Her2/neu, as biological markers, have been included to determine clinical prognostic staging more accurately. In addition, the use of genetic biomarkers is recommended when it is possible. Three of them (*ESR1*, *PGR*, and *KIF2C*) have already been included in the AJCC recommendations [40]. The known biological functions and pathways that are encoded by certain biological markers enable their use to predict

clinical outcomes as well as the evaluation of therapeutic possibilities. In another study, Zhou et al. [41] examined gene expression data from the TCGA database of BC patients. Analyses identified several important differentially expressed genes, of which *ABC₃*, *CCL₂₂*, *FOXJ₁*, *IL₇RN*, and *MAP2K6* were factors associated with good prognosis, while *KCNIP₃* and *MRPL₁₃* were associated with poor prognosis of the BC patients.

This study has some limitations. First, although the criteria for inclusion of the participants in this study were clear and meticulously respected, it is still impossible to completely avoid that all participants in the study did not have any additional malignant or unconfirmed inflammatory disease. Second, except for age and menopausal status, other clinical data on patients is lacking. The lack of data on parity, body mass index, hormone replacement therapy, alcohol and tobacco use, diet, and physical activity limits our ability to have a clearer picture of the risk factors that affect the occurrence of BC, and at the same time, it limits our ability to assess the eventual correlation between IL-7 and these risk factors.

Conclusion

Observing the significant increase in the IL-7 serum level in the EIBC patients as compared to the healthy control group, it can be assumed that IL-7 can be used as a potential indicator for the diagnosis of BC. The lack of correlation with tumor size, lymph node metastasis, and all other histopathological characteristics of the tumor, maybe due to the production of IL-7 by immune system cells and not by tumor cells, questions its use as a prognostic indicator. The re-evaluation of the IL-7 serum levels of the patients participating in this study in the near future, as well as during follow-up, would enable assessing the correlation between IL-7 serum level and potential disease recurrence and, at the same time, evaluate the possibility of using it as an independent prognostic factor. With a reconfirmation of the correlation between IL-7 and BC through a study in a larger number of patients as well as the eventual correlation with the recurrence of the disease, the investigation of IL-7 as a proinflammatory cytokine could be tested as a poor prognostic factor and could help us to stratify the risk of recurrence. On the other hand, it could be used to follow up on the patients after oncological treatment. However, further studies with an even larger number of participants should be performed in order to determine the origin of IL-7, whether it is from BC cells or from the immune system cells, as well as to see the correlation between IL-7 serum levels and other interleukins.

Abbreviations

EIBC: Early invasive breast cancer; BC: Breast cancer; IL-7: Interleukin-7; IL-7R: Interleukin-7 receptor; IL1RN: Interleukin-1 receptor antagonist; PI3K: Phosphoinositide 3 kinase; JAK-1: Janus kinases-1; JAK-3: Janus kinases-3; STAT-5: Signal transducers and activators of transcription-5; CNS: Central nervous system; CCL22: C-C motif chemokine ligand 22; EMT: Epithelial mesenchymal transition; ESR1: Estrogen receptor 1; PI3K/Akt: Phosphoinositide 3-kinase/protein kinase B; Akt: Protein kinase B (serine/threonine-specific protein kinase); ABC₃: ATP-binding cassette protein 3; FOXO1: Forkhead box protein O1; FOXJ1: Forkhead box J1; PR: Progesterone receptor; PGR: Progesterone receptor (GeneCards); KIF2C: Kinesin family member 2C; KCNIP3: Potassium voltage-gated channel interacting protein 3; ER: Estrogen receptor; MDC5: Myeloid-derived suppression cells; MAP2K6: Mitogen-activated protein kinase 6; MRPL13: Mitochondrial ribosomal protein L13; Treg: T regulatory cells; AJCC: American Joint Committee on Cancer System; TNM: Tumor node metastasis; NST: No special type; IDC: Invasive ductal carcinoma; ILC: Invasive lobular carcinoma; LVI: Lympho-vascular invasion; PNI: Perineural invasion; ASCO: American Society of Clinical Oncology; WHO: World Health Organization; IARC: International Research Agency; SEER: Surveillance, Epidemiology, and End Results; NCI: National Cancer Institute; ENCR: European Network of Cancer Registries; SLNB: Sentinel lymph node biopsy; UHCZ: University Hospital Center Zagreb; FISH: Fluorescent in situ hybridization; CISH: Chromogenic in situ hybridization.

Acknowledgements

We are grateful to the nurses and all the patients who contributed to this paper.

Authors' contributions

The design, data analysis, and initial manuscript are done by Faton Sermahaj. Natalija Dedić Plavetić has participated in the study design and revision of the manuscript. Ljubica Radmilović Varga, Marina Popović, Davor Mijatović, and Besim Sermahaj participated in the data collection. Statistical analyses were performed by Ugur Gozalan and Slavica Sović. Mentor Sopjani participated in figure preparation and correcting and finalizing the revised manuscript. All authors read, commented, and approved the final manuscript.

Funding

The authors received no financial support for the research, authorship, and/or publication of this article.

Availability of the data and materials

The datasets generated and/or analyzed during the current study are available in the [Harvard Dataverse] repository, "The Role of Serum Interleukin-7 level as Biological Marker in Breast Cancer" (<https://doi.org/10.7910/DVN/YG30LR>), Harvard Dataverse, DRAFT VERSION, UNF:6:3:dNeDrCcWjX4fc5DDUllua.

Declarations

Ethics approvals and consent to participate

The study has been carried out in compliance with the Code of Ethics of the Helsinki Declaration, as well as the ethical approval from both institutions: Ethics committee of the University Clinical Center of Kosovo (no. 913/2; 30 October 2017) and the University Clinical Center Zagreb (no. 02/21 AG; 02 November 2017). All the participants have been informed about the aim of this study along with safety and security considerations prior to signing the informed consents, as study prerequisites. Moreover, they have been informed about the right to withdraw and ask for their data to be destroyed.

Consent for publication

Not applicable.

Competing interests

The authors declare that they have no competing interests.
