A chiroptical approach for the absolute stereochemical determination of *P*-stereogenic centers†

Debarshi Chakraborty,^a Hadi Gholami,^{‡a} Aritra Sarkar,^a Leo A. Joyce,^{§b} James E. Jackson^{¶a} and Babak Borhan^{¶*a}

A simple chiroptical solution for the absolute stereochemical determination for asymmetric phosphorus V stereocenters is presented. Strong coordination of the phosphorus oxide with the Zn-metallo center of the racemic host Zn-MAPOL 2 leads to an induced axial chirality of the host, yielding a strong ECCD signal. A mnemonic is proposed to correlate the asymmetry of the guest molecule with the observed ECCD signal.

Introduction

Optically active compounds containing *P*-stereogenic centers are of great importance and have been widely applied as chiral ligands, organocatalysts, and versatile synthons.¹ Furthermore, a number of biologically active molecules, agrochemicals, and pharmaceuticals possess *P*-chirogenic centers.^{1a} With the progress in asymmetric synthesis, access to these compounds has become more routine.² Despite these recent advancements, there is a dearth of straightforward methods for the rapid stereochemical determination of these *P*-stereogenic centers.

Current methods rely on X-ray crystallography, optical rotation, 2D NMR spectroscopy, and chemical derivatization to known compounds.³ These methods are generally slow and not a simple solution for most cases. Well diffracting crystals are required for X-ray analysis, a slow and laborious process that depends on the propensity of the molecule to form suitable crystals. Homochiral *ortho*-palladated complexes have been employed as a “reporter complex” to establish the stereochemistry of *P*-chiral compounds using 2D NMR spectroscopy.^{3a,3g} These complexes bind with chiral phosphines, leading to diastereomeric forms that generate unique ¹H NMR signals. Although this methodology has enjoyed some success, it is limited to symmetrically substituted bis or polydentate phosphines. Binding of non-symmetric bisphosphines leads to

the formation of regio-isomers that complicates absolute stereochemical determination. Chiral mono-phosphines pose a more difficult problem due to their high rotameric lability that leads to ambiguous determination of absolute stereochemistry. Mislow and coworkers used ‘intersystem matching’ to correlate the Cotton effects seen for chiral sulfoxides to assign the absolute stereochemistry of analogous phosphine oxides.⁴ Nonetheless, the absolute stereochemistry of the sulfoxides is needed for this method. Zygo *et al.*⁵ utilized VCD to solve this problem for a single substrate, although, it has yet to become a routine method for this class of compounds. The difficulty often stems from the inability to predict an accurate set of solution phase conformers, due to the flexibility of the molecules and complexity of their structures.

With our prior experience in using porphyrin-based hosts as reporters of chirality, we set our goal to develop a simple, rapid, direct (derivatization free), and micro-scale methodology to assign the chirality of *P*-stereogenic compounds. We envisioned utilizing the principles of Exciton Coupled Circular Dichroism (ECCD) to develop a procedure that addresses this long-standing problem. This method enables the non-empirical assignment of helicity for two or more interacting chromophores *via* coupling of their electric transition dipole moments.⁶ The porphyrin tweezer methodology, a host-guest interacting system, has been used successfully for the absolute stereochemical determination of various functionalities.⁷ Porphyrin tweezers are achiral, but highly chromophoric host systems that are able to adopt a specific helicity upon binding chiral guest molecules.

Results and discussion

The helicity of the porphyrin tweezer (*P* or *M*), derived from the ECCD signal, leads to the assignment of stereochemistry of the bound chiral molecule. A major limitation in using the tweezer strategy is the need for bidentate coordination with the guest

molecule to induce helicity within the host/guest complex. Mono-phosphine oxides lack the presence of a secondary coordination site and also do not possess a suitable functional group to append the required secondary binding element. Recently, our group has developed a new host system MAPOL 1,⁸ having a rigid bis-phenol backbone which brings two porphyrins in closer proximity compared to a traditional tweezer, thus creating a smaller cavity. MAPOL 1, adopts a 1 : 1 mixture of its *P* and *M* stereoisomers at room temperature (Fig. 1). This equilibrium is shifted in one direction through its interaction with a chiral guest molecule. Using this concept, MAPOL 1 has been successfully implemented as a reporter of chirality for chiral monoamines.⁸ Translation of point to axial chirality through hydrogen bonding interaction between the phenolic hydrogen atoms in the host with the chiral amine guest was the key to its success.

On the other hand, Zn-MAPOL 2, the zincated version of host MAPOL 1 bears two orthogonal binding elements *i.e.* hydrogen bonding with phenolic functionality and complexation with the zinc metal center (Fig. 1). Although for cyanohydrin both hydrogen bonding and ligand coordination to Zn metal-center was necessary,⁹ chiral sulfoxides required coordination of the sulfoxide oxygen atom to the Zn metal to induce helicity of Zn-MAPOL 2 (Fig. 1).¹⁰ Intrigued by the results observed with sulfoxides, we realized that a similar approach might provide an effective chiroptical solution for the absolute stereochemical assignment of *P*-chiral phosphorus oxides. Coordination between the Zn²⁺ and the oxygen atom should yield a tightly bound host-guest complex, leading to the induction of axial chirality in the host molecule. Moreover, with recent advances in conversion of phosphine oxides to phosphines with stereochemical fidelity,^{2g-i,11} a routine method for the absolute stereochemical determination of phosphine oxides remains a critically important, but yet an unmet need.

First, we turned our attention to UV-vis measurements to explore the binding of phosphine oxides to Zn-MAPOL 2. Addition of phosphine oxide *R_P-4d* to Zn-MAPOL 2 led to a redshift from 413 nm to 423 nm, indicating the binding event between the host and the guest molecules (Fig. S1†). Titration of Zn-MAPOL 2 with different equivalents of *R_P-4d* provided

Fig. 1 MAPOL and its analogs, used in the absolute stereochemical determination of amines, cyanohydrins, and sulfoxides.

a binding isotherm revealing a K_{assoc} of $\sim 2.7 \times 10^5 \text{ M}^{-1}$ in hexane (Fig. S2†), while Job plot analysis indicated the formation of a 1 : 1 complex (Fig. S3†).

Gratifyingly, a strong negative ECCD signal ($A = -667$) was observed when only 5 equivalents of compound *R_P-4d* was added to a solution of Zn-MAPOL 2 (1 μM) in hexane at 0 °C (Fig. 2). This low detection limit is the consequence of the high binding affinity for phosphine oxides with Zn-MAPOL 2. As anticipated, a positive ECCD signal was observed for *S_P-4c*, the enantiomer of *R_P-4d* (Table 1). The strength of the ECCD signal was sensitive to the temperature of measurement. As expected, the ECCD amplitude decreased with increasing temperature (Fig. S24†). Nevertheless, a significant signal is observed even at 45 °C, also indicative of the strong binding between the host and guest molecule.

With these preliminary results in hand, a variety of molecules possessing an asymmetric phosphorus oxide moiety with different alkyl and aryl substituents were synthesized according to reported procedures.^{2a,12} Complexation of these *P*-stereogenic compounds with Zn-MAPOL 2 resulted in strong ECCD signals centered around the Soret band of the host system (Table 1). In general, all *S_P* phosphorus oxides produce positive ECCD spectra while *R_P* phosphorus oxides yield negative ECCD spectra. Binding of *R_P-4d* with methoxy Zn-MAPOL 3 produced a complex spectrum, (Fig. S31†) suggesting the presence of the hydroxyl groups in host 2 is necessary to yield a consistent ECCD signal. This observation can be explained based on the fact that intramolecular hydrogen bonding between the hydroxyl groups at 2,2' positions of the host system helps in rigidifying the favored CD active conformer.

In order to derive a binding model for the host-guest system, numerous attempts to obtain a single crystal of any of the host-guest complexes were unfruitful. Nonetheless, the crystal structure of the phosphine oxide *R_P-4d* bound to the Zn-tetraphenylporphyrin (Zn-TPP) as a mimic of the porphyrin ring in Zn-MAPOL 2 was obtained (Fig. 2). The crystal structure confirmed the coordination between the oxygen atom in

Fig. 2 A strong ECCD signal ($A = -667$) is observed upon binding of *R_P-4d* (5 equiv.) to Zn-MAPOL 2. The crystal structure of *R_P-4d* bound to Zn-TPP is suggestive for the binding conformation of the phosphine oxide bound to Zn-MAPOL 2.

^a A corresponds to the amplitude for the ECCD spectrum, while A_{corr} is the amplitude after correction for the enantiopurity. ^b 5 equiv. of phosphine oxide. ^c 20 equiv. of phosphine oxide.

phosphine oxide and the zinc metal of the metal porphyrin. It also revealed that upon coordinating with the zinc center, the chiral phosphine oxide *R_P-4d* projects its smallest substituent (the methyl group) towards the porphyrin ring (Zn–O–P bond angle is 138°), thus projecting the medium and larger group away (Fig. 2). As depicted in Fig. 3, coordination of the oxygen lone pair with the Lewis acidic Zn center orients the guest molecule *R_P-4d* in between the two porphyrin rings of Zn-MAPOL 2. Minimization of steric interactions leads to Zn-MAPOL 2 adopting a specific helicity. While the small methyl group is projected towards the bound porphyrin, the other two substituents are pointed towards the unbound porphyrin. An energetically minimized conformer would be achieved by

Fig. 3 Putative binding of *R_P-4d* to Zn-MAPOL 2, illustrating the competing diastereomeric forms [*P*-(*R_P*) and *M*-(*R_P*)]. Considering the binding paradigm in Fig. 2, with the small methyl group directed towards the porphyrin ring bound to the phosphine oxide, the projection of the medium (propyl) and the large (phenyl) groups towards the second porphyrin leads to the prediction for the preponderance of the *M*-helicity (relieving strain associated with the large phenyl group). As observed experimentally, this arrangement would predict a negative ECCD spectrum.

placing the larger phenyl group (based on A strain values¹³) in a less sterically hindered space, thus favoring the *M*-(*R_P*) complex. As such, the *M* helicity is energetically favored, leading to a negative ECCD signal. The latter speculation agrees with the observed ECCD signal for the complex of *R_P-4d* with Zn-MAPOL 2 (Fig. 2). The predicted signs of all phosphine oxides 4a–4f, based on their A strain values, are in full agreement with the experimentally observed values (Table 1). The Zn-MAPOL 2 host system is capable of discerning small differences with ease. For example, steric differentiation of methyl and ethyl, or phenyl and *o*-anisyl, leads to large ECCD signals, although their sizes are not significantly different (Table 1). A note regarding substituents that do not have a reported A strain value; in such cases, we rely on prediction of size based on the relative size of the substituent, favoring the decision on factors that affect A strain values the most. These factors are the nature of the first atom at the point of attachment (degree of substitution), and its associated bond length.¹³

The successful application of Zn-MAPOL 2 to determine the absolute configuration of simple phosphorus oxides prompted the investigation of more complex substrates to examine the generality and applicability of this methodology. Compound *R_P-4g* and its epimer *S_P-4h* (epimeric at the *P* center only) bear multiple stereocenters. Nonetheless, they produced opposite ECCD signals when complexed with Zn-MAPOL 2, thus highlighting the sensitivity of the system to the asymmetry at the *P*-chiral center (Table 1). The same binding model as described above (Fig. 3) also predicts the absolute stereochemistry of these two epimers based on the size of the substituents in the order of Ph > OMe > Me (as described above, OMe is perceived to be smaller than Ph although its A strain value is not known). Expanding the substrate scope with compound *R_P-4i*, which has

a hydrogen atom in place of the Me group in R_P -**4g** (Ph > OMe > H), produced the anticipated ECCD signal (Table 1).

Next, the system was challenged with molecules that not only contain multiple stereocenters, but also have coordinating functionalities, which have the potential to bind with the zincated porphyrin. This would demonstrate the practical use of Zn-MAPOL 2 with a pharmaceutical API with a complex structure. Hence, we decided to analyze sofosbuvir **5**, a commercial antiviral agent, widely used for the treatment of hepatitis C virus (HCV).²¹ The absolute stereochemistry of **5** was determined previously by X-ray crystallography.¹⁴ In addition to the phosphoramidate functionality, sofosbuvir **5** contains hydroxyl, ester, fluoride, and imide moieties, which could bind to the zincated porphyrin. Nonetheless, we posited that the strong binding affinity for phosphorus oxide complexation with the zincated porphyrin ($\sim 270\,000\text{ M}^{-1}$) should prevent interference from other groups. As a point of comparison, to date we have found amines and sulfoxides as the strongest binders of Zn-TPP, with binding affinities of $\sim 11\,000$ – $15\,000\text{ M}^{-1}$.^{7b,10} Complexation of Sofosbuvir **5** with Zn-MAPOL 2 in hexane resulted in a strong positive ECCD signal (Fig. S13†). Unexpectedly, *epi*-sofosbuvir (*epi*-**5**), epimeric only at the *P*-stereocenter, also resulted in a positive ECCD signal (Fig. S14†), albeit with lower amplitude. We proposed that although various functional groups in sofosbuvir **5**, such as the ester, imide, fluoride, or hydroxyl, would have a substantially reduced binding affinity in comparison to the phosphoramidate, the presence of the second metalloporphyrin does not preclude the potential dual binding of other functional groups. In fact, the initial strong binding of the phosphoramidate would entropically favor the binding of another functional group with the second porphyrin.

We surmised that the use of the non-interacting solvent, hexane, increases the availability for binding of a second functionality. It is noteworthy that the metalloporphyrin strategy (*i.e.*, the porphyrin tweezer methodology or the Zn-MAPOL system) for absolute stereochemical determination of most functional groups fails in polar solvents, presumably because of the attenuated binding affinities, either as a result of solvation of the functional group, and/or competing solvent coordination with the metalloporphyrin. Nonetheless, the high binding affinity of the phosphoramidate moiety with the zincated porphyrin suggests a solution to remove secondary interactions that originate from less efficient binding functionalities. The use of a more polar solvent would not only solvate the interfering groups, but also, would decrease their binding affinity with the zincated porphyrin. This would eliminate the secondary interaction that interferes with desired sole stereodifferentiation based on the asymmetry of the *P* chiral center.

After a quick survey, chlorinated solvents, such as dichloromethane, chloroform, and chlorobenzene provided the best balance, where sofosbuvir **5**, maintained its positive ECCD signal when bound to Zn-MAPOL 2, while complexation of *epi*-**5** resulted in a negative ECCD signal (Fig. 4). The binding model follows the mnemonic proposed above (Fig. 3), in which the smallest group (phenoxy) on the *P*-stereogenic center points towards the bound porphyrin ring, while the medium (amino ester) and large (uracil) substituents on the phosphorus atom project towards the unbound porphyrin ring (note that the

Fig. 4 Sofosbuvir and *epi*-sofosbuvir bound to Zn-MAPOL 2 lead to positive and negative ECCD, respectively. The sign of the ECCD spectra depends solely on the absolute stereochemistry of the *P*-chiral center. The helicity of **2** is correlated to the absolute stereochemistry of the phosphorus atom by applying the mnemonic described in Fig. 3, considering the large (L), medium (M), and small (OPH, S) as depicted in the structure of sofosbuvir **5**.

assignment of size here is based on our perceived notion of volume, since A strain values are not available for complex substituents as those found in **5**). This leads to the prediction of a positive ECCD signal for **5**, as observed experimentally. Expectedly, a counterclockwise twist would be favored in the binding of *epi*-**5** with Zn-MAPOL 2, yielding a negative ECCD signal. Indeed, the measured ECCD signals are in full agreement with the proposed binding scenario (Fig. 4).

The use of Zn-MAPOL 2 as a ‘reporter of chirality’ was extended to the chiroptical sensing of *P*-chiral bis-phosphine oxides, molecules that are important in asymmetric catalysis.¹⁴ The bidentate coordination of bis-phosphine oxides with Zn-MAPOL 2 was anticipated, putatively leading to even a stronger complex as compared to the binding of monophosphorous oxides. The investigations were initiated with the complexation of R_P,R_P -**6c** with Zn-MAPOL 2, which led to the generation of a strong ECCD signal ($A = -3460$, Fig. 5a). Due to strong binding affinities, only 1 equivalent of the substrate ($\sim 0.5\ \mu\text{g}$ of sample, 1 nmol, 1 μM) is necessary to obtain ECCDs with large amplitudes for all of the bis-phosphine oxides examined. Compound S_P,S_P -**6a**, easily obtained from the oxidation of DIPAMP,¹⁵ also generates the anticipated ECCD signal (Table 2), illustrating the practical applicability of the methodology for the absolute stereochemical determination of chiral bis-phosphines that are widely used in transition metal catalysis. As expected, its enantiomer R_P,R_P -**6b** yields a negative ECCD signal of similar intensity.

Fig. 5b depicts the proposed mnemonic for stereodifferentiation that leads to the observed ECCD spectra. We assume each phosphorus center dictates the orientation of the attached porphyrin independently, leading to a preferred helicity of the host system. As such, each porphyrin binds the

Fig. 5 (a) Compounds R_P,R_P -**6c** and R,R -**6f** bound to Zn-MAPOL **2** lead to negative and positive ECCD, respectively; (b) the helicity of **2** is dictated by the chirality at each P -center. The two substituents R_L and R_S point to the most sterically available quadrant, with R_S closer to the biphenol linker; (c) a similar mnemonic is proposed, with the diphenyl substituents on the P -center oriented in the most sterically available quadrant, while R_L and R_S are positioned to have the least interaction with the biphenol linker.

phosphorus center in a manner to minimize interactions with the larger of the two substituents (2-Me-C₆H₄ vs. Ph, R_P,R_P -**6c**). Note that in this mnemonic the chain connecting the two phosphorus centers is not part of the stereodifferentiation. Also important is the fact that the two substituents on the phosphorus center are oriented away from the biphenol linker in order to reduce steric interactions. R_P,R_P -**6c** represented in Fig. 5b, leads to a counter-clockwise rotation of the two porphyrin rings with respect to each other, thus predicting a negative ECCD (M -helicity), in accordance to the experimentally observed signal.

Thus far, all of the examples have demonstrated ‘chiral sensing’ of molecules with an asymmetric phosphorus atom. Nonetheless, an important cohort of the bidentate phosphorus ligands are not asymmetric at the P -center, but rather the adjacent carbon atom. An example is Chiraphos,¹⁶ which upon routine oxidation (H₂O₂)^{11c} yields the bis-phosphine oxide R,R -**6f**. Illustrated in Fig. 5a, complexation of 1 equivalent of R,R -**6f** with Zn-MAPOL **2** yields a positive ECCD signal ($A = +3110$). Table 2 lists a number of these molecules (**6d–6g**) complexed with Zn-MAPOL **2**, where consistently strong ECCD signals were observed. Fig. 5c depicts the proposed binding model that yields the predicted helicity of the complex. Similar to the model described above, the phenyl substituents on the phosphorus atom are placed in the most sterically unencumbered space, while R_L and R_S (the large and small α -carbon substituents, respectively) dictate the helicity by avoiding interactions with the biphenol linker (the small group points towards the linker). In the mnemonic developed for R,R -**6f** (Fig. 5c), this leads to a clockwise (P -helical) orientation of the porphyrins, matching the experimentally observed positive ECCD signal.

Table 2 ECCD of chiral bis-phosphine oxides bound to Zn-MAPOL **2**

Entry	Predicted sign	λ nm, $\Delta\epsilon$	A/A_{corr}^a
 S_P,S_P - 6a	Positive	427, +416 418, -196	+612
 R_P,R_P - 6b	Negative	427, -426 418, +228	-654
 R_P,R_P - 6c	Negative	429, -1838 420, +1622	-3460
 R - 6d	Positive	429, +332 421, -254	+586

 R,R - 6f	Positive	427, +1862 419, -1248	+3110
 S,S - 6g	Negative	427, -1350 418, +804	-2154

^a A corresponds to the amplitude for the ECCD spectrum, measured with the addition of 1 equiv. of the bis-phosphine oxide to a 1 μM Zn-MAPOL **2** solution.

Conclusions

In conclusion, we have developed a simple chiroptical based methodology for the direct assignment of absolute stereochemistry of chiral phosphorus compounds without the need for derivatization. The protocol is suitable for the stereochemical determination of phosphorus stereocenters in mono-phosphine oxides, phosphinates, phosphoramidates, as well as bis-phosphine oxides, chiral at either the P -center or the α -carbon. High binding affinities enable the detection of stereochemistry for P -stereogenic center of molecules with multiple functionalities that could also bind with the zincated porphyrin. Simple mnemonics for each class of molecules correlates the observed ECCD signal with the stereochemistry.

Conflicts of interest

The authors declare no conflict of interest.
