ABSTRACT

The search for therapeutic drugs that can neutralize the effects of COVID-2019 (SARS-CoV-2) infection is the main focus of current research. The coronavirus main protease (M_{pro}) is an attractive target for anti-coronavirus drug design. Further, α -ketoamide is proved to be very effective as a reversible covalent-inhibitor against cysteine proteases. Herein, we report on the non-covalent to the covalent adduct formation mechanism of α -ketoamidebased inhibitor with the enzyme active site amino acids by QM/SQM model (QM = quantum mechanical, SQM = (200×10^{-3})) semi-empirical QM). To uncover the mechanism, we focused on two approaches: a concerted and a stepwise fashion. The concerted pathway proceeds via deprotonation of the thiol of cysteine (here, Cys145 SYH) and simultaneous reversible nucleophilic attack of sulfur onto the α -ketoamide warhead. In this work, we propose three plausible concerted pathways. On the contrary, in a traditional two-stage pathway, the first step is proton transfer from $Cy_{145} S_{\gamma}H$ to $His_{41} N\delta$ forming an ion pair, and consecutively, in the second step, the thiolate ion attacks the α -keto group to form a thiohemiketal. In this reaction, we find that the stability of the tetrahedral intermediate oxyanion/hydroxyl group plays an important role. Moreover, as the α-keto group has two faces Si or Re for the nucleophilic attack, we considered both possibilities of attack leading to S- and R-thiohemiketal. We computed the structural, electronic, and energetic parameters of all stationary points including transition states via ONIOM and pure DFT method. Additionally, to characterize covalent, weak noncovalent interaction (NCI) and hydrogen-bonds, we applied NCI-reduced density gradient (NCI-RDG) methods along with Bader's Quantum Theory of Atoms-in-Molecules (QTAIM) and natural bonding orbital (NBO) analysis

1. Introduction

A new human coronavirus (HCoV), SARS-CoV-2, began spreading in December 2019 in Wuhan City, China causing pneumonia called COVID-19. All the affected countries are trying to prevent the spread of the new mysterious coronavirus. Despite this, the number of infected persons is continually increasing each day. As the viral maturation mainly relies on the M_{pro} 's activity, the coronavirus main protease (M_{pro}) (also called 3C like protease or $3CL_{pro}$) is also an attractive target for anti-CoV drug design. Recently, it is reported that deadlier coronavirus is highly similar with 96% sequence identity to that of the SARS-CoV M_{pro} [1]. Due to this worldwide pandemic, considerable research is focused to design many inhibitors for the novel coronavirus [2–10]. For drug designing, the reversible covalent inhibitors are generally more preferable than irreversible ones due to its risks in long term treatment and side effects [11–14]. In addition to the development of novel drugs, researchers look for effective substances among drugs that are already approved or developed for other purposes.

Covalent inhibitors, that bind with cysteine proteases, are generally substrate with an electrophilic center, including Michael acceptor (-CH=CH-CO-), aldehydes (-CH=O), nitriles (-C=N), vinyl sulfone ($-SO_2$ -CH=CH₂), and α -ketoamide (-CO-CO-NH-) [15-22]. Of them, α -ketoamide proved to be very effective against cysteine proteases [23]. The advantage of the α -ketoamides is that their warhead can interact with the catalytic center of the target proteases by two hydrogen-bonding interactions, namely, via the α -keto oxygen and amide oxygen [1]. Whereas, warheads like aldehydes or Michael acceptors interacts with the catalytic center by only one hydrogen bond, the α -ketoamide motif is emerging as the most promising group with a possible reversible inhibition of the enzyme's activity better than the other investigated C-terminus warheads [23,24] The α-keto group of the α -ketoamide forms a reversible tetrahedral adduct with the active cysteine enzyme. For example, calpain I inhibitors form tetrahedral hemiketal adduct by the cysteine residue (Cys₁₁₅) onto the α -keto group

Received 11 August 2020; Received in revised form 20 November 2020; Accepted 23 November 2020 Available online 28 November 2020 0301-4622/© 2020 Elsevier B.V. All rights reserved. of the α -ketoamide [25]. Chen J-C et al. [26] synthesized a series of small molecules bearing an α -ketoamide warhead and evaluated for their ability to inhibit cathepsin S. In another study, Ota. E. et al. [27] showed that thienyl-substituted α -ketoamide is a less hydrophobic reactive group for photo-affinity labeling. Recently, Hilgenfeld and his coworkers [1,28], designed a series of α -ketoamide as inhibitors of SARS-CoV-2 Mpro.

Whereas, few theoretical studies about the reaction mechanism of a

similar many researches are present in literature [29–39], including the interesting work of Zanetti-Polzi et al. [40] and Arafet et al. [41], but precise reaction mechanism of α -ketoamide and cysteine is rarely reported [42]. It is essential to understand the inhibitory action of these drugs to design a more promising drug against coronavirus. Commonly, it is believed that in these mechanisms, the first step is deprotonation of thiol of cysteine with a basic side chain, usually by a histidine residue followed by a nucleophilic attack of the anionic sulfur onto the α -keto group of the inhibitor forming an S—C covalent bond and an oxyanion.

cysteine protease with Michael acceptor, aldehydes, and nitriles and

Scheme 1. Proposed concerted reaction mechanism between the active site of SARS-CoV-2 M_{pro} and α-ketoamide inhibitor-warhead from Si face based on the present calculations.

In the last step, the oxyanion gets stability by hydrogen bonds and/or by accepting a proton. To date, few studies have been made to understand how the keto group binds with the cysteine proteases. In particular, to the best of our knowledge, the literature lacks the detailed quantum chemical study of α -ketoamide based inhibitors.

In the present paper, for the first time, we will investigate the detailed reaction mechanism for the conversion of noncovalent adduct to covalent adduct by the interaction of Mpro of coronavirus and two α -ketoamide compounds with the help of semi-empirical and density functional (DFT) studies. We extracted these compounds from the pdb file 6y2f and 5n19 (henceforth, we name them as S-In and R-In). We considered two approaches for the reaction: i) a concerted and ii) a stepwise mechanism. In the first case, the nucleophilic attack and such proton transfer occur in a single step. Herein, we considered four pathways, for example, Pathways 1–3, as shown in Scheme 1. On the other hand, the second case involves a two-step process (Pathway 4). In the first step, a zwitterionic ion pair ($\mbox{CysS}^-/\mbox{HisN}^+$) is formed from the fast proton transfer from cysteine (Cys₁₄₅) to nearby histidine residue (His₄₁) (Scheme 2). In the second step, the thiolate anion of cysteine $Cys_{145} S^-$ will then attack the α -keto group of the inhibitor to form a C—S covalent bond and an oxyanion, followed by abstraction of a proton from the nearest base histidine (His₄₁) (Scheme 2). Moreover, as shown in Fig. 1, the α -keto group has *Re* and *Si* faces for the nucleophilic reaction. Thus, addition from Re and Si faces leads to R- and S- stereochemistry adducts. All the adducts, formed by pathways 1-4, caused by the attack from Si face and hence have S stereochemistry. Additionally, using SARS-CoV Mpro, we also considered the attack of Cys S from Re face leading to R-thiohemiketal. However, for the Re face reaction, we only examined the reaction by thiolate nucleophile ($Cys S^{-}$) (Scheme 3). Finally, to find out the stability of R- and S- thiohemiketal and the oxyanion/hydroxyl group, we will apply modern theoretical tools like NCI-reduced density gradient (NCI-RDG) methods along with Bader's Quantum Theory of Atoms-in-Molecules (QTAIM) and natural bonding

orbital (NBO) analysis.

2. Method and computational studies

Here, we applied ONIOM-QM/SQM model (QM = quantum mechanical; SQM = semi-empirical QM) treating the protease and inhibitor computationally. In this model, we have considered a large number of atoms from the nearest interacting amino acids as shown in Fig. 2. Here, to fulfill the need, we consider only the active species and key hydrogen bonding interactions. We have used hybrid B3LYP [43,44] and Semiempirical PM6 [45] level of theory (ONIOM-B3LYP/6-31G(d):PM6) [46] for optimization. To avoid the expensive QM/SQM molecular dynamics method, here we explored the reaction mechanism in static conditions. For the more accurate single-point energy calculation, we used dispersion corrected @B97X-D/6-31G(d,p):PM6 level of theory on the B3LYP/6-31G(d):PM6 optimized geometries. Hydrogens were used as link atoms. We performed all calculations unless indicated otherwise, by using the Gaussian 09 suite of programs [47]. The effect of the low polarity protein environment, on the active-site model, was estimated by performing single-point calculations using the polarizable continuum model (PCM) with UAKS radii [48] method at the same level of theory as the geometry optimizations. The dielectric constant was set to the standard value $\varepsilon = 4$ to represent this environment [49].

The QM/SQM energies were calculated using the following equation as the separate energies of a QM calculation on the QM region (E_{model} , QM) and an SQM calculation on the whole system (E_{real} , SQM) minus an SQM calculation on the QM region (E_{model} ,MM). The use of such ONIOM model is capable of optimizing and characterizing all critical structures properly along with the energy profile.

The energy is calculated using the following equation:

$$E(ONIOM) = E_{real}(SQM) - E_{model}(SQM) + E_{model}(QM)$$
(1)

Scheme 3. Proposed two-step reaction mechanism between the active site of SARS-CoV M_{pro} with α -ketoamide inhibitor-warhead from the *Re* face to generate R-thiohemiketal based on the present calculations.

To explore the activation energy barrier of each step and the energy profile, we optimized all the intermediate and transition state (TS) geometries. We found no imaginary frequencies for the geometries of minima indicating that the obtained stationary points are the local minimum at potential energy surface (PES). On the other hand, only one imaginary frequency at the TS geometry demonstrated that this geometry is a first-order saddle point on the PES. To verify the reliability of the TSs, intrinsic reaction coordinates (IRC) were also computed. Natural bond orbital (NBO) [51] analysis at B3LYP/6-31G(d) level was carried out to understand the orbital interactions and charge delocalization for the title complexes. In such analysis, NBOs are first defined for each covalent bond, lone pair, and anti-bonding orbital by using the molecular orbitals obtained by quantum-chemical calculations, and the orbital interaction energies are subsequently computed for all possible interactions between electron-donor Lewis-type NBO (i) and acceptor non-Lewis NBO (j). For each electron-donor NBO (i) and electron-

Fig. 2. Schematic diagram indicating the atoms of the S- and R-thiohemiketal adducts taken from pdb code a) 6y2f and b) 5n19. Green lines indicate hydrogen bonds. Not all atoms are shown for the sake of clarity. Red rectangles indicate the α -ketoamide inhibitor-warhead of interest in the present paper. The figure is drawn with ligplot [50]. acceptor NBO (j), the stabilization energy $E^2{}_{ij}$ associated with delocalization $i \to j$ is calculated as

$$\frac{\mathbf{E}^{2}_{ij}=\mathbf{q}_{i}\mathbf{F}(\mathbf{i},j)^{2}}{\mathbf{\epsilon}_{j}-\mathbf{\epsilon}_{i}}$$
(2)

where q_i is the donor orbital occupancy, ε_i and ε_j are orbital energies, and F(i,j) is the off-diagonal NBO Fock matrix element.

Additionally, we used a powerful tool NCI-RDG method to distinguish and visualize weak interactions: stabilized (hydrogen bonding), destabilized (steric repulsion) and delocalized weak (van der Waals). Specifically, the plot of S and sign($\lambda 2$) ρ reveals troughs, which signify the different noncovalent interactions. The troughs corresponding to attractive interactions (such as H-bonds) lie in the region of negative sign($\lambda 2$) ρ , whereas repulsive interactions lie in the positive region.

The initial structure of coronavirus protease is extracted from the crystallographic data of the ligand-free enzyme of the SARS-CoV-2 (2019-nCoV) main protease (pdb:6y2e). Furthermore, the initial structure of the enzyme-inhibitor complexes are obtained from the crystallographic data of R- and S-adduct of SARS-CoV and SARS-CoV-2, respectively, main protease and α -ketoamide inhibitor using 6y2f and 5n19 pdb files from the protein data bank.

Now in the simplified model, during optimization, there may be possibilities to collapse the rigid enzyme structure leading to unrealistic structure. To prevent this, we kept some atoms fixed based on the parameters found in the crystal structure. The inclusion of such constrain allows obtaining a more realistic rigid structure. However, such constrain optimization sometimes leads to small frequencies, but here, as the number of frozen atoms is very small, in few structures, we obtained imaginary frequencies, that too below 2 cm⁻¹, and thus neglected.

Here, the mechanism determined based on the reduced model of inhibitor that involves only small portion (warhead) of the full molecule bound in the X-ray structure of M_{pro} can be different from the final mechanism once substituents responsible for the recognition process are attached to the α -ketoamide warhead. Additionally, as recently demonstrated [52] change of the chemical surrounding can meaning-fully influence the electrophilic character of the carbon atom and in consequence the reaction barrier.

3. Results and discussion

3.1. Structure of the inhibitor-free enzyme and α -ketoamide

As stated above, we started our investigation with the crystal structure of ligand-free M_{pro} (pdb:6y2e). Initially, the protonation and crude optimization were performed using the H++ web server at pH 7.3 to mimic the experimental conditions [53]. Then, we optimized a truncated version of the enzyme by using some active site selected residues including His₄₁, Gly₁₄₃, Ser₁₄₄, Cys₁₄₅, His₁₆₄, and His₁₆₅. Our objective is to understand the characteristics and relative strength of hydrogen bonds and other non-covalent interactions occurring in the active part of the enzyme in the absence of the warhead of inhibitor.

Fig. S1 (in supporting information) shows that the H-bond network among the residues in the active site creates a pocket large enough to accommodate the α -ketoamide. Also, we detect the other intermolecular interactions as depicted by NCI-RDG isosurface plot (shown in Fig. S1b by red arrows) and important bond critical point (bcp) indicating the inter-residual H-bonds, along with a cage critical point (Fig. S1c, green sphere).

Additionally, to compare the structure of enzyme-inhibitor complex and inhibitor-free enzyme, we have deleted the inhibitor from the enzyme-inhibitor complex (6y2f) and compare the structure with free enzyme active sites as shown in Fig. S2. Aiming to have a complete overview of the α -ketoamide inhibitor, we optimized a simple α -ketoamide N-methyl-2-oxopropanamide. We find that there are three possible isomers of α -ketoamide C₁, C₂, and C₃ (Fig. 1b). Obviously, the C₃ isomer is more stable than the other two isomers C1 and C2, in this case, by 9.75 kcal/mol computed at b3lyp/6-31G(d) level for the presence of H-bond of 2.20 Å. The natural population analysis (NPA) shows that the natural charge on amidic carbon is +0.58e while that on α C is +0.52e. However, the molecular electrostatic potential (MEP) plot shows that αC is more electrophilic than that of amidic carbon. The results show that HOMO-LUMO energy gap of this molecule is 4.86 eV and the isosurface plot of HOMO and LUMO are depicted in Fig. 1d. Interestingly, the LUMO of S—In contains the π^* orbital for accepting nucleophile, while in R-In, the π^* orbital is located on LUMO+1 (See Fig. S3).

Herein, the His41 protonated in ε -position instead of δ was used. The protonation of His₄₁ in ε -position prevents this residue from being directly involved in the proton transfer from Cys₁₄₅, the role that was

demonstrated in studies on proteolysis in Mpro [37].

3.2. Reaction mechanism of α -ketoamide with M_{pro} from Si face to form S-thiohemiketal

3.2.1. Pathway 1: concerted self-catalyzed reaction without water and histidine as a function of the shuttle

Herein, the system contains 68 atoms and as the system is small, we have applied DFT method on the whole system. In this mechanism, first, a non-covalent enzyme-inhibitor complex EI1 is formed. Then, this complex proceeds to form a tetrahedral complex (Int1) via a transition state (TS₁), by nucleophilic attack of Cys_{145} S onto αC atom, with a simultaneous transfer of a proton from SH to O. We optimized all these geometries (Fig. 3) and for only TS_1 , we found one imaginary frequency of -1332 cm^{-1} indicating a sharp TS, and the animation at this mode corresponds to the change in the reaction coordinate as stated above. No imaginary frequencies are observed for EI₁ and Int₁. In EI₁, the S-H and C=O bonds are oriented in parallel, with Cys_{145} S atom pointing at αC and thiol H atom pointing at O(α C) atom. The S- α C and H-O(α C) bond distances are 2.23 and 2.55 Å, respectively. We identified a bond critical point bcp between incoming S and electrophilic α C by applying QTAIM analysis. The electron density (ρ), Laplacian of electron density ($\nabla^2 \rho$), and energy density (H(r)) are 0.0479, 0.2949, and - 0.0068 a.u. The positive sign of $\nabla^2 \rho$ and negative sign of H(r) supports a non-covalent nature of the S-aC interaction. We find a donor-acceptor NBO pair ns $\rightarrow \pi_{C=O}^*$ with delocalization energy of $E^2 = 50.4$ kcal/mol. NBO charge analysis also shows that the natural charge on sulfur increases from 0.213e in EI1 to 0.254e in TS1, and subsequently, on the $O(\alpha C)$, the negative charge increases from -0.332e (in EI1) to -0.357e in TS1 indicating a charge transfer from Cys_{145} moiety to the α -ketoamide. In **TS**₁, these bond distances are reduced to 1.92 and 1.43 Å, respectively. At TS1, two important NBO pairs are detected (Table S1 and Fig. 4): the first one is $n_{O(\alpha C)} \rightarrow {\sigma_{S-H}}^{\star}$ which indicates the S—H bond cleavage O—H bond formation, and the second one $n_{O(\alpha C)} \rightarrow \sigma_{N\delta-H}^*$ supports that His₄₁, by forming H-bonds with O(α C), helps to make the α C more electrophilic and thus more susceptible to the nucleophilic attack (Fig. 3). The geometry at αC changes from planar to tetrahedral as the reaction proceeds from **EI**₁ to **TS**₁ to **Int**₁. In **Int**₁, the values of ρ , $\nabla^2 \rho$, and H(r) at the bcp on S- αC bond are 0.1631, -0.2526, and -0.1336. The negative sign of $\nabla^2 \rho$ and H(r) indicates the covalent nature of C—S bond. The energy barrier (Eact) for this mechanism is 21.0 kcal/mol computed at @B97X-D/6-31G(d,p)//B3LYP/6-31G(d):PM6 and the reaction are excergic, $\Delta_r E \approx 25.1$ kcal/mol. However, in the protein environment at $\epsilon = 4$, the energy these values are lowered, for example, E_{act} and $\Delta_r E$ are ca. 19.1 and - 13.1 kcal/mol, respectively (Fig. 5 and Table 1).

3.2.2. Pathway 2: concerted water-assisted reaction without histidine as a function of a shuttle

To model this approach, we propose that the reaction started from the initial inhibitor-enzyme complex EI₂, which is formed by the interaction between active site amino acids and inhibitor. Herein, the system contains 77 atoms and as the system is small, we have applied DFT method on the whole system. In this case, a water molecule serves as a shuttle to transfer proton of Cys₁₄₅ SH to α-keto oxygen. As the reaction proceeds, EI2 transforms to tetrahedral-intermediate Int2 via the 6membered transition state TS_2 . The TS_2 is characterized by an imaginary frequency of -567 cm^{-1} , and the imaginary mode clearly identified that the TS corresponds to the synchronous process of proton transfer and nucleophilic attack. Importantly, here, His145 functions as an H-bond donor and not as a proton shuttler. The optimized geometries along with important geometrical parameters of EI2, TS2, and Int2 are shown in Fig. 6. In EI₂, the critical S-αC distance is 2.07 Å and becomes shorter to reach 1.96 Å at TS₂ and 1.88 Å in Int₂. In EI₂, we find a bcp between S and αC with ρ and $\nabla^2\rho$ values of 0.0923 and 0.4328 a.u. The non-negative value of $\nabla^2 \rho$ supports the non-covalent interaction of S and α C. On the other hand, in **Int**₂, the negative values of $\nabla^2 \rho$ and H(r) are indications of the covalent nature of C-S bond. In TS₂, the water molecule is assisting the proton-transfer by bridging between $O(\alpha C)$ and Cys₁₄₅ S, with two H-bonds of 1.64 and 1.50 Å, respectively.

The NBO analysis shows that, in EI₂, the main donor-acceptor NBOs $n_S \rightarrow \pi_{\alpha C=O}^*$ (E² = 101.4 kcal/mol) clearly indicates the attack of Cys₁₄₅ S to α C of ketoamide (Fig. 4). Also, in TS₂, we properly identified three main donors -acceptor NBO pairs $n_S \rightarrow \sigma_{\alpha C=O}^*$, $n_S \rightarrow \sigma_{O-H(W)}^*$, and n_O $(\alpha C) \rightarrow \sigma_{O-H(W)}^*$ indicating the participation of water in the transition states (See Fig. 4 and Table S1). Furthermore, the NBO charge analysis shows that, in the conversion of EI₂ to TS₂, the charge transfer on S is not significant, whereas, the negative charge on $O(\alpha C)$ changes from -0.339e to -0.440e indicates that the protonation of O(α C) initiates the nucleophilic attack. However, we note that, in this pathway, the overall resemblance between Int₂ and crystallographic structure (See Figs. 6 and 10, later) is not good. For example, S-C distance in Int₂ is 1.88 but the crystallographic distance is 1.81 Å. Similarly, there a moderate disagreement in the H-bond network between the His₄₁ and tetrahedralintermediate. The calculated energy of TS2 is 2.0 kcal/mol in the gas phase and 1.8 kcal/mol at $\varepsilon = 4$ relative to EI₂ (Fig. 5 and Table 1). This step is also highly excergic of -27.5 and -4.2 kcal/mol in the gas phase and 4, respectively.

3.2.3. Pathway 3: concerted reaction with two water and histidine as a function of shuttle

In this approach, we assumed that the concerted proton transfer and nucleophilic attack is assisted by two water molecules and the nearby neutral N ϵ protonated His₄₁ residue (see Scheme 1). Herein, the system contains 63 atoms and as the system is small, we have applied DFT

The $\Delta E_{act(reverse)}$ values are relative to their corresponding enzyme-inhibitor covalent complexes, for example, for TS₁, $\Delta E_{act(reverse)}$ value is calculated relative to Int₁.

^b Data within the bracket are relative to Int₃.

method on the whole system. The optimized structure of the enzymeinhibitor complex EI₃ is shown in Fig. 7. In EI₃, two water molecules bridges between Cys145 SH and His41 6NH with three H-bonds of 1.75, 1.31, and 1.47 Å. The reactant proceeds from EI₃ to Int₃ via TS₃. We detect a bcp at **EI**₃, between S and α C with ρ , $\nabla^2 \rho$, and H(r) values of 0.0540, 0.3303, and - 0.0121 a.u., indicating non-covalent nature of the bond. To support from NBO study, we find a donor-acceptor NBO pair ns $\rightarrow \sigma_{\alpha C=0}^*$ of E² = 57.1 kcal/mol. The optimized **TS**₃ is characterized by an imaginary frequency of $208i \text{ cm}^{-1}$. The vibrational movement at imaginary mode indicates the simultaneous transfer of a proton from Cys₁₄₅ SH to His₄₁ δN via two bridging water molecules W₁ and W₂ together with the nucleophilic attack by the Cys_{145} SH onto the αC of the inhibitor. Additionally, the donor-acceptor properties, involved in TS₃, are well supported by the NBO analysis (Fig. 4). We find that, in TS₃, four important NBO pairs, namely, $n_S \rightarrow \sigma_{O-H(W1)}$, * $n_{O(W1)} \rightarrow \sigma_{O-H(W2)}$, * $n_{N\delta} \rightarrow \sigma_{O-H(W2)}$,* and $n_S \rightarrow \sigma_{\alpha C-O}$ * well supports the donor and acceptor atoms. The optimized geometries show that the main distance S- α C in reduces from 2.23 Å at EI₃ to 2.18 Å in TS₃, 1.97 Å in Int₃, and 1.83 Å in Int3', and consequently, the $\alpha C\text{-}O^-$ increases from 2.22 to 2.24 to 2.28 to 2.41 Å. Furthermore, Int₃ is a tetrahedral oxyanion-intermediate stabilized by three H-bonds: $His_{41} \ \epsilon H \cdots O^-, \ W_3 \ H \cdots O^-,$ and intramolecular α -amidic H···O⁻ with 2.16, 1.76 and 2.31 Å, respectively. Similar to the previous pathways, here also, the non-covalent S-C bond becomes covalent in Int₃ ($\nabla^2 \rho \approx -0.2321$, H(r) ≈ -0.1240 a.u.). The energy barrier for this step shows 4.9 kcal/mol relative to EI₃ in the gas phase. While the reaction is barrierless ($E_{act} = -1$ kcal/mol) at the protein

environment $\varepsilon = 4$ (Table 1). Finally, the intermediate Int₃ converts to Int₃' by transferring a proton from His₄₁ δN to oxyanion formed by αC . We consider two paths for such proton transfer: direct and watermediated, and consequently, we obtained two corresponding transition states TS_{3 pt} and TS_{3 ptw} as shown in Fig. 7. TS_{3 pt} and TS_{3 ptw} are characterized by the imaginary frequencies of 416*i* and 313*i* cm⁻¹, respectively. The transition state TS_{3 pt} shows that the transferring proton is exactly shared by the imidazole N δ of His₄₁ and the oxyanion. In **TS_{3 pt}**, we detect an NBO pair $n_{N\delta} \rightarrow \sigma_{O-H}^*$ of $E^2 = 230.1$ kcal/mol to support the donor-acceptor properties. In TS_{3_ptw}, the two important NBO pairs are $n_{O(W3)} \to {\sigma_{N\epsilon-H}}^{*}$ and $n_{O(\alpha C)} \to {\sigma_{O-H(W3)}}^{*}$ with delocalization enrgy of 149.6 and 263.1 kcal/mol. Energy profile diagram shows that proton transfer for via TS_{3_ptw} is more preferable (E_{act} \approx 2.9 kcal/mol) than via TS_{3 pt} ($E_{act} \approx 14.2$ kcal/mol) in protein environment at $\varepsilon = 4$. Furthermore, the results indicate that, in the gas phase, the ion pair Int₃ is less stable, by ca. 1.4 kcal/mol, than its neutral counterpart Int₃' while the reverse is true in continuum solvent model, that is, at $\varepsilon =$ 4, Int₃ is more stable than Int₃' by ca. 1.4 kcal/mol. In Int₃', the S- α C distance is 1.83 Å. The computed structure of Int₃' almost resembles the crystallographic structure within the full enzyme environment.

3.2.4. Pathway 4: stepwise process using histidine as proton donor-acceptor

3.2.4.1. First-step. Herein, the system contains 74 atoms and as the system is small, we have applied DFT method on the whole system. As stated in the introduction, the first step is the proton transfer from Cys₁₄₅ SH to Nɛ protonated His₄₁ Nδ. Before starting the calculation, for correct protonation site and fixing any missing atoms at experimental pH 7.3, we run the crystallographic molecule in H++ server. The results show that, in the crystal, the distance between Cys_{145} sulfur and $\text{His}_{41}\ N\delta$ $(S \dots N\delta)$ is 4.94 Å, and this is too large to transfer. The results of H++ server also show that the S-H bond is oriented in such a direction from where the proton transfer is not possible. Besides, as the nearest water molecule, H₂O₆₃₇ (in pdb:6y2e), is 3.49 Å away from the Nɛ atom of His₄₁, to overcome the problem, we include an explicit water molecule in the proton transfer. Therefore, herein, a water-mediated proton transfer is assumed to occur. Fig. S2 shows that there is a rotation of the imidazole ring to accept the inhibitor. Thus, it can be hypothesized that, in the presence of inhibitor, because of the rotamer of either the imidazole ring of His_{41} or C—S of Cys_{145} (as shown in Fig. S4) or by both, the distance between the donor atoms Cys S and His No becomes 3.54 Å. This distance favors the proton transfer to form CysS⁻/HisH⁺ ion pair. To optimize and characterize all critical structures properly along with the energy profile and to find the transition state as a first-order saddle point, we used the minimum number of proteins as in the catalytic triad (His₄₁, Cys₁₄₅, and His₁₆₄) along with Met₁₆₅ and two water molecules $(W_1 \text{ and } W_2)$. We define the reaction proceeds from the reactant complex

Fig. 6. Optimized geometries of the intermediates and transition state of the concerted water-assisted reaction (as in Pathway 2) between M_{pro} and α -ketoamide of the inhibitor from Re face. Atoms marked with asterisks are fixed during geometry optimization. For the sake of clarity, only polar hydrogen atoms are shown.

Fig. 7. Optimized geometries of the intermediates and transition state of the concerted reaction according to Pathway 3 between M_{pro} and α -ketoamide of the inhibitor from *Re* face. Atoms marked with asterisks are fixed during geometry optimization. For the sake of clarity, only polar hydrogen atoms are shown.

 (R_z) to the ion-pair product complex E_z via the transition state (TS_z) . As shown in Fig. 8, in optimized R_z , the water molecule W_1 connects the donor atoms Cys_{145} S and His Nõ with two H-bonds of 1.69 and 2.04 Å, respectively, by forming a bridge. The transition state TS_z is characterized by an imaginary frequency of $-117~{\rm cm}^{-1}$. In TS_z , the bridging W_1 has two O—H distances of 1.26 and 1.17 Å. The S—H distance is increased from 1.40 Å in R_z to 1.68 Å in TS_z to 3.09 Å in E_z . The animation of imaginary mode surely indicates the transfer of the proton from donor to acceptor. Also, in the TS, the NBO pairs $n_S \rightarrow \sigma_{O-H}{}^*$ and $n_{N\delta} \rightarrow \sigma_{O-H}{}^*$ clearly shows that proton transfer from Cys_{145} SH to His_{41} δN (Fig. 4 and Table S1).

The activation barrier of the proton transfer is about 2.5 kcal/mol at $\varepsilon = 4$, while this value is high (12.1 kcal/mol) in the gas phase (Table 1 and Fig. 5). As shown in Table 1, this value is comparable with the recent works [41,54] where the authors showed the inhibition of SARS-CoV-2 M_{pro} with Michael acceptors. However, our study shows that this step is exotheric for α -ketoamide as an inhibitor of M_{pro}. The process is an exoergic process of about -13.1 kcal/mol at $\varepsilon = 4$. These results are also in agreement with the previously reported data for another similar nitrile-based inhibitor [29].

3.2.4.2. Second-step. Herein, the system contains 115 atoms and as the

system slightly is large, we applied DFT method α -ketoamide, Cys₁₄₅ and His₄₁ residues. For other residues, we have applied PM6 method. In this step, the Cys₁₄₅ thiolate ion, formed in by the previous step, attacks the α -keto of the inhibitor to form a C—S covalent bond. In this model, to find the reaction profile, we increase S-C distance gradually, as the reaction coordinate, from 1.73 Å to 3.30 Å with an increment of 0.1 Å at each step (Fig. S5). The result shows that the guess transition structure is at about 2.22-2.23 Å and accordingly, we found the correct transition state TS_4 , which is characterized by an imaginary frequency of 109icm⁻¹. Unfortunately, from the IRC calculation, we could not obtain the initial enzyme-inhibitor complex EI4. From the S-C surface scan, we assumed EI4 that resides very close to TS4 in the PES, and thus, we optimized EL4 with a constant distance of 2.33 Å. The optimized structures of the stationary points are shown in Fig. 8. In EI₄, the α -keto oxygen is stabilized by a strong hydrogen bond of 1.69 Å from His_{41} N ϵ . Also, one crystalline water molecule stabilizes the amidic oxygen to make the α C more electrophilic. Notably, the animation of imaginary mode shows that, at the TS, the attacking of Cys_{145} and transfer of a proton from His_{41} N ϵ to α -keto oxygen occurs synchronously. Additionally, we find two main NBO pairs $n_S \rightarrow \sigma_{\alpha C-O}^*$ and $n_{N\epsilon} \rightarrow \sigma_{O-H}^*$ to support the donor-acceptor properties (Fig. 4 and Table S1). Finally, TS4 converts to tetrahedral thiohemiketal Int_4 , where the S- α C bond distance becomes 1.83 Å from 2.22 Å in TS₄. Consequently the αC-O

Fig. 8. Optimized geometries of the intermediates and transition state of the two-step concerted reaction according to Pathway 4 between M_{pro} and α -ketoamide of the inhibitor from *Si* face. Atoms marked with asterisks are fixed during geometry optimization. For the sake of clarity, only polar hydrogen atoms are shown.

Fig. 9. Optimized geometries of the intermediates and transition state of the reaction between M_{pro} and α -ketoamide of the inhibitor from *Re* face. Atoms marked with asterisks are fixed during the geometry optimization. For the sake of clarity, only polar hydrogen atoms are shown.

increases from 1.24 to 1.33 to 1.39 Å as the reaction proceeds from EI₄ \rightarrow TS₄ \rightarrow Int₄. Here also, the covalent nature of Int₄ is confirmed from their $\nabla^2 \rho$, and H(r) values, -0.1663 and -0.0922 a.u. The results show that all the structural parameters of Int₄ resemble well the crystallographic data (Figs. 8 and 10). The energy barrier of the step is low *ca*. 1 kcal/mol both at $\varepsilon = 1$ and 4. The conversion EI₄ \rightarrow Int₄ is exothergic of -9.9 and -19.2 kcal/mol in the gas phase and $\varepsilon = 4$, respectively. The exoergicity is similar to the recent work [41,54] for the inhibition with Micheal acceptors with a similar kinetically controlled sulfur-carbon bond formation reaction.

3.3. Reaction mechanism of α -ketoamide with M_{pro} from Re face to form R-thiohemiketal

Herein, the system contains 95 atoms and as the system is small, we have applied DFT method on the whole system. To model this reaction mechanism, we used the crystal structure of SARS coronavirus main protease in complex with the alpha-ketoamide of R-thiohemiketal (pdb:5n19). We assume that the reaction started from the initial enzyme-inhibitor complex EI₅ (Fig. 9). Compare to the Si face reaction with CoV-2 M_{pro}, here, S...C distance is significantly longer, ca. 3.09 Å. To verify whether S and αC are in fact interacting or not, we detect a bcp between them with ρ , $\nabla^2 \rho$, and H(r) values are 0.0048, 0.0381, and 0.0024 a.u. Besides, we detect a donor-acceptor NBO pair $n_S \rightarrow \pi_{\alpha C-O}^*$ with low delocalization energy of 8.3 kcal/mol. Both the QTAIM and NBO analysis indicates that the interaction between Cys S and αC is very weak and non-covalent in nature. Interestingly, as the Cys145 thiolate approaches the α -keto of the inhibitor from *Re* face, both the attacking nucleophile and the electrophilic-warhead, experience completely different interacting sites from the Si face reaction. For example, in EI₅, amide oxygen is stabilized by His₄₁ Nɛ with a H-bond of 2.36 Å. Similarly, the oxygen of α -keto group is stabilized by the H-bonds from the donor atom of Cys₁₄₅, Gly₁₄₃, and one water (W₁) with bond distances of 2.90, 2.23, and 2.38 Å, respectively. The reaction proceeds from EI₅ to transition state TS_{5} to tetrahedral intermediate $Int_{5}.$ The transition state is characterized by one imaginary frequency of 81*i* cm⁻¹ and the animation of the imaginary mode correctly corresponds to the nucleophilic attack of S⁻ on α C. We find an NBO pair $n_S \rightarrow \pi_{\alpha C-O}^*$ to support the direction of electron migration at TS (Fig. 4 and Table S1). With the progress of the reaction, the main distance S- α C decreases from 3.09 Å in EI₅ to attain 2.59 Å in TS₅, and 1.89 Å in Int₅, and thereby, the change of hybridization at αC is from sp² to sp³ to form an oxyanion (which we will discuss later in detail). Consequently, the α C-O⁻ increases from 2.21 (in EI₅) to 2.22 (in TS₅) to 2.30 Å (in Int₅), however, this is not shown in Fig. 9 for clarity. The optimized structure of Int₅ shows that the oxyanion is stabilized by strong H-bonds from Cys145, Gly143, and W1 of 1.66, 2.07, and 1.71 Å, respectively. Notably, as stated above, Int₅ has R-stereochemistry. At Int₅, the values of $\nabla^2 \rho$, and H(r) of bcp are negative which again supports the covalent nature of S-C bond. To verify the validity of the computed results, we protonated and optimized the oxyanion of Int₅ (named as Int₅-H), and compared it with the crystallographic result. The computed results resemble closely that of the experimental data. For example, the main covalent bond distance S- α C is 1.82 in Int₅-H is good agreement with the experimental data 1.80 Å [1]. Also, all the H-bonds are in close agreement with the crystallographic data as shown in Figs. 9 and 10. The energy barrier this reaction is 4.6 kcal/mol in gas phase and 6.8 at $\varepsilon = 4$ (Fig. 5 and Table 1). Like the reaction from Si face, here also, the reaction is exoergic of 24.8 kcal/mol in enzyme environment. However, in the gas phase, exoergicity is lowered.

3.4. The noncovalent interaction and stability of oxyanion/hydroxyl group of R- and S-thiohemiketal

To explore the noncovalent interactions including H-bonding to the oxyanion, we extracted the crystal structure and added hydrogen atoms in the missing position and reoptimized with respect these added hydrogen. In order to examine the oxyanion, first, we tried to optimize the geometry by deleting the proton on oxyanion, but, in case of Sadduct, all attempt to obtain oxyanion in presence of His₄₁ NEH are failed, resulting in the transfer of proton from NE H to O⁻. However, in this adduct, we notice that the hydroxyl group is stabilized by four nearby polar atoms, namely, NE of His₄₁, amide H of warhead, and slightly by H of accessible H₂O (W₁) and another amide H of inhibitor (See Fig. 10). The corresponding distances are 1.72, 1.77, 2.96, and 3.00 Å, respectively. Notably, only two of them form hydrogen-bonds with the oxyanion as evident from Bader's QTAIM plot (Fig. 10b), and the orientation of non-covalent interaction is such that a hydroxyl group is formed. We detected two bcps, namely, cp1 and cp2, correspond to two strong H-bonds with the electron densities of 0.0513 and 0.0458 a.u., respectively. Also, we computed the H-bond energy associated with the bcps. To calculate the H-bond energy, we used the following latest formula derived by Emamian et al. [55] at the very accurate CCSD(T)/julcc-pVTZ level including basis set superposition error (BSSE) bond correction as well as SAPT2 + (3)&MP2/aug-cc-pVTZ level, the latter allows the bond energy to be decomposed into physically meaningful components to shed light on the electronic nature of the considered hydrogen bond interactions:

Hydrogen bond energy (kcal/mol) = $-223.08 \times \rho_{hen}$ (a.u.) +0.7423 (3)

Furthermore, the amidic oxygen is stabilized by NH of triad residues Cys₁₄₅-Ser₁₄₄- Gly₁₄₃, forming three H-bonds of 2.06, 2.77, and 1.88 Å, respectively. These H-bonds are characterized by three bcps, namely, cp₃, cp₄, and cp₅, and their respective ρ and $\nabla^2 \rho$ values are shown in Table 2. The computed H-bond energy of them are -3.60, -2.09, and -6.21 kcal/mol, respectively. Thus, such a huge stability, by the H-bonds, of the α -ketoamide warhead reminds us of the advantage of the α -ketoamide compared to the other inhibitor-warhead.

Fig. 10c and d show a scatter plots of RDG S vs sign($\lambda 2$) ρ and colorfilled RDG isosurfaces depicting noncovalent interaction region. Although we obtained several π - π , CH- π , and H-bond interactions from the calculations, we discussed only the interactions related to α -ketoamide motif.

The thiohemiketal of R stereochemistry experiences completely an opposite interacting residues due to the addition of incoming nucleophile from *Re* face. For example, the hydroxyl group at thiohemiketal forms three hydrogen bonds, with the triad residues Cys₁₄₅-Ser₁₄₄-Gly₁₄₃ at M_{pro}, of 1.99, 3.09, and 2.52 Å, respectively, and additionally, forms another H-bond with crystallographic water W₁ (Fig. 10a). The QTAIM analysis (Table 2) found three are bcps, namely, cp₁, cp₂, and cp₃ correspond to the H-bonds α -keto O-Cys₁₄₅ NH, α -keto O-Gly₁₄₃ NH, and α -keto OH-W₁ O but not with the Ser₁₄₄ residue. For these H-bonds bonds, the H-bond energy computed according to Eq. (3) are -4.79, -1.08, and - 5.43 kcal/mol, respectively.

Besides, unlike S-adduct, the amidic oxygen is stabilized by a very strong H-bond with His₄₁ NeH of 1.40 Å. The QTAIM result shows that the ρ and $\nabla^2\rho$ values at the bcp (cp₄) are 0.0850 and 0.3334 a.u., respectively. Obviously, the H-bond energy is also high: -18.21 kcal/mol.

Finally, the covalent nature of S- αC bond in both the thiohremiketal, R- and S- stereochemistry, is characterized from their bcps (cp₅ and cp₆) and their ρ and $\nabla^2\rho$ values. The covalent bond is usually characterized by a negative Laplacian and a negative energy density. Here, for the R-adduct, the energy density and $\nabla^2\rho$ values are -0.1052 and -0.1884 a. u., respectively, while for the S-adduct, the energy density and $\nabla^2\rho$ values are -0.0980 and -0.1718 a.u., respectively.

4. Conclusion

In the present paper, we report a theoretical investigation of the reaction mechanism of α -ketoamide based inhibitor with coronavirus

Fig. 10. Hydroxyl group of the R- and S-thiohemiketal of the 5n19 and 6y2f crystal structures, respectively. a) H-bonds between the oxygen atoms of hydroxyl group and amide moiety in warhead with the hydrogen atoms of coronavirus enzyme residue. b) Some selected QTAIM bond critical points indicating by orange sphere. main protease M_{pro} by using DFT and semi-empirical quantum mechanical method within ONIOM model. Our calculation was based on the crystal structure of free coronavirus protease (pdb:6y2e) and the coronavirus-inhibitor complexes of both S and R stereochemistry (respectively, pdb:6y2f and pdb:5n19).

We fulfilled main objectives, namely, to characterize of the noncovalent and covalent interactions between the enzyme active site and inhibitor warhead by using NCI-RDG and Bader's QTAIM, and to uncover the mechanism of thiohemiketal formation between cysteine protease and α -ketoamide inhibitor.

Apart from the common two-step pathway *via* CysS⁻/His41⁺ ion pair formation (pathway 4), we propose three more concerted pathways without forming an ion pair. We have identified and characterized all the stationary points including intermediates and transition states on the PES. Since for the reversible covalent-inhibitor, the change of non-covalent to covalent state is crucial [40], we identified each state properly by applying AIM and NBO analyses.

The computed kinetic and thermodynamic parameres show that although Pathway 1 has a high activation barrier, pathway 2 and 3 have comparable activation barriers with the traditional pathway 4. Also, all these steps are highly exoergic due to the high stability of the oxyanion/hydroxyl group. Nevertheless, the exoergicity of pathway 3 is slightly less (*ca.* -4.2 kcal/mol) making the ΔE_{act} of the reverse reaction, that is, Int₃ \rightarrow EI₃, low (*ca.* 2.8 kcal/mol). This indicates the reversible binding nature of the inhibitor. Another notable feature, derived from PCM calculation at $\varepsilon = 4$, is that for all except *Re* face reaction, the nucleophilic-attacking steps have higher $\Delta_r E$ in the gas phase. This is probably due to greater stabilization of non-covalent enzyme-inhibitor complex (reactant side) than that of covalent S-thiohemiketal complex (product side).

In conclusion, our computed results suggest that in addition to the traditional mechanism (pathway 4) the reaction can also proceed *via* the other plausible paths with similar activation barriers.

In the α -ketoamide, the LUMO is π^* in nature and resides on α -keto group to accept a lone-pair of electrons from Cys S. Interestingly, here, the LUMO of S—In contains the π^* orbital for accepting nucleophile, while in R-In, the lowest energy π^* orbital is located on LUMO+1 for such acceptance.

Finally, we have found that in R-thiohemiketal, the α -keto oxygen in the oxyanion/hydroxyl group is stabilized by three hydrogen bonds, while for S-thiohemiketal, the α -keto oxygen is stabilized by two H-bonds but slightly stronger than in R-thiohemiketal. As a result, in both adducts, the sulfur forms S—C covalent bond of similar strengths.

Indeed, the application of an extensive QM/MM approach by using full enzyme residues may slightly alter the position of potential energy surfaces from our results, that is, using static calculation; however, we hope that our model is sufficiently accurate for this work.

In the present situation, we believe that our work is providing extremely relevant and useful information for designing new anticoronavirus drug using α -ketoamide as an inhibitor.
