Abstract: The SWI/SNF chromatin-remodeling complex plays an essential role in several cellular processes including cell proliferation, differentiation, and DNA repair. Loss of normal function of the SWI/SNF complex because of mutations in its subunits correlates with tumorigenesis in humans. For many of these cancers, cytotoxic chemotherapy is the primary, and sometimes the only, therapeutic alternative. Among the antineoplastic agents, anthracyclines are a common treatment option. Although effective, resistance to these agents usually develops and serious dose-related toxicity, namely, chronic cardiotoxicity, limits its use. Previous work from our laboratory showed that a deletion of the SWI/SNF factor *SNF2* resulted in hypersensitivity to doxorubicin. We further investigated the contribution of other chromatin remodeling complex components in the response to cytotoxic chemotherapy. Our results indicate that, of the eight SWI/SNF strains tested, *snf2*, *taf14*, and *swi3* were the most sensitive and displayed distinct sensitivity to different cytotoxic agents, while *snf5* displayed resistance. Our experimental results indicate that the SWI/SNF complex plays a critical role in protecting cells from exposure to cytotoxic chemotherapy and other cytotoxic agents. Our findings may prove useful in the development of a strategy aimed at targeting these genes to provide an alternative by hypersensitizing cancer cells to chemotherapeutic agents.

Keywords: chromatin remodeling, cancer, DNA damage/repair, heat-shock response, oxidative stress

Introduction

Chromatin remodeling plays a crucial role in gene expression. The SWI/SNF complex was identified in *Saccharomyces cerevisiae* by mutations, which resulted in altered regulation of the *HO* gene that encodes a site-specific endonuclease required for gene switching at the *MAT* locus through the generation of a DNA double-strand break, preventing a mating-type switch.¹ Similarly, defects in the expression of the *SUC2* genes encoding the invertase sucrose hydrolyzing enzyme² were found to be the result of mutations in *SNF* (sucrose nonfermenting) genes,³ and were first linked with chromatin through the study of suppressors of defective subunits of the complex.⁴ In vitro DNase accessibility assays confirmed that the SWI/SNF complex could modify the histone-DNA structure,⁵ while in vivo studies proved that SWI/SNF activity allows for increased access of polymerases and transcription factors to DNA.⁶

Chromatin remodeling involves biochemical modifications to histones, including methylation, acetylation, and phosphorylation.⁷ These various modifications affect the chromatin status, affecting large regions of the genome.^{8,9} The SWI/SNF

chromatin-remodeling complex is essential in several cellular processes including cell proliferation, differentiation, and DNA repair.¹⁰ Loss of normal function of the SWI/SNF complex as a result of mutations in its subunits correlates with tumorigenesis in humans,¹¹ and the status of some of the subunits, such as BRG1 and BRM, can serve as prognostic indicators in patients diagnosed with certain cancers. Individuals whose cancers were positive for both nuclear BRG1 and BRM had a 5-year survival of 72% compared with 33.6% for those with loss of these ATPases.¹² The SWI/SNF complex has been implicated in the development of cancer, as its subunits have been shown either to function as tumor suppressors or to interact with known tumor suppressors and oncogenes.¹³ The cancers with the highest rates of mutations on SWI/SNF were ovarian clear cell (75%), clear-cell renal carcinoma (57%), hepatocellular carcinoma (40%), gastric cancer (36%), melanoma (34%), and pancreatic cancer (26%). Across all tumor types, the average frequency of SWI/SNF mutations (19%) approached that of TP53 (26%), the single most mutated tumor suppressor gene.¹⁴

Anthracycline antibiotics are commonly used as anti-cancer agents for a wide range of solid tumors and hematological neoplasias. Although initially an effective therapy, drug resistance can develop during the course of treatment. Anthracycline resistance cannot be overcome by increasing the dose due to the increased risk of serious side effects, such as the development of dilated cardiomyopathy.¹⁵ Cytotoxic therapy is still a relevant therapeutic approach, and efforts to make it more effective and less toxic remain an important goal.

We previously reported a genome-wide genetic screening in *S. cerevisiae* that identified 71 deletion strains displaying varying levels of sensitivity to doxorubicin. Of these, the *snf2* deletion, involving a gene that encodes components of the SWI/SNF complex, showed significant sensitivity.¹⁶ To further investigate the contribution of chromatin remodeling factors in the survival of cells exposed to cytotoxic stresses, we evaluated the survival of SWI/SNF mutant strains treated with the commonly used chemotherapeutic agents, doxorubicin and cisplatin, and other cytotoxic stresses that mediate the action of these agents, such as oxidative stress, DNA damage, and protein denaturation (heat). Our results indicate that, of the eight SWI/SNF strains tested, *snf2*, *taf14*, and *swi3* were the most sensitive mutants, and suggest that the potential targeting of the human homologues may result in cancer cells' hypersensitization to chemotherapy, while deletion of *SNF5* rendered cells resistant to some cytotoxic agents.

Materials and methods

General genetic methods and strains

Yeast extract/peptone/dextrose (YPD; 1% yeast extract, 2% peptone, 2% dextrose, and 2% agar) and synthetic complete (0.67% yeast nitrogen base without amino acid, 0.087% amino acid mixture, 2% dextrose, and 2% agar) media or the corresponding drop-out media were as described.^{17,18} Homozygous haploid deletion strains library (parental strain BY4741: *MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0*) was obtained from Thermo Fisher Scientific (Waltham, MA, USA). The gene deletions present in the strains used in this study have been validated by polymerase chain reaction (data not shown).

Chemicals

Yeast nitrogen base, yeast extract, peptone, and dextrose were purchased from Thermo Fisher Scientific (Waltham, MA, USA); doxorubicin-HCl (2 mg/mL) and cisplatin (1 mg/mL) were obtained from Bedford Laboratories (Eatontown, NJ, USA); and menadione sodium bisulfite was purchased from Sigma-Aldrich (St Louis, MO, USA). Working solution concentrations were as follows: doxorubicin (20 μmol/L), cisplatin (80 μmol/L), menadione (6.6 mmol/L), and etoposide (1 mmol/L), prepared under sterile conditions. The concentrations of the drugs used were selected to only marginally affect the wild-type (WT) strain, but be very toxic to the control strains. Drugs were aliquoted and stored at -20°C.

Sensitivity of strains to chemotherapeutic agents and cytotoxic stressors

The concentration of the drugs used for strain exposure was determined experimentally using the WT parental strain BY4741 as previously described.¹⁶ Briefly, single colonies were grown overnight in liquid YPD media, at 30°C with shaking. Cells were then washed and resuspended in ultrapure sterile water. Strains were then separated into control and treatment groups, and exposed to drug or vehicle for 3 hours. After exposure, the cells were once again washed and suspended in sterile water. Serial dilutions were spotted onto YPD agar plates and incubated at 30°C. Heat-shock treatment was performed by plating serial dilutions of the strains and incubating at 37°C. Cell growth was monitored daily, and colonies were counted at day 3. Survival was calculated relative to the corresponding untreated control, and sensitivity was determined relative to the survival of the WT strain. Survival, as indicated in the "Results" section, is specific for that drug concentration. Each trial involved the testing of five independent colonies for each cytotoxic

agent, and three trials were performed. The survival of the WT strain was defined as 100% to be able to calculate the survival between the different trials for each drug as well as to compare the sensitivity of the strains to different drugs.

Statistical analysis

Data analysis and graphing was performed using the Graph-Pad Prism 4 software package. Specific analysis for each experiment is indicated in Figures 1–5. The mean of at least three trials is plotted, together with the standard deviation. Differences between mean values and multiple groups were analyzed by one-way analysis of variance (ANOVA). Statistical significance was set at $P < 0.05$.

Results

Determination of the sensitivity of SWI/SNF deletion strains to chemotherapeutic agents doxorubicin and cisplatin

To determine the contribution of the factors comprising the chromatin remodeling complex (SWI/SNF complex) to the response to chemotherapeutic agents, we determined the survival of single-gene deletion mutants after exposure to doxorubicin and cisplatin. The concentration of the drugs used in the assays was determined empirically using the WT strain (BY4741) and corresponding positive controls (sensitive strains) as indicated in the “Materials and methods” section. There are eleven genes that encode for components of the SWI/SNF complex in *S. cerevisiae*, as indicated in Table 1. The deletion strains used are derived from the parental strain (BY4741) and are haploids. For this reason, the role of three genes could not be tested because their deletion strains were nonviable (*ARP7*, *ARP9*, and *SWI10*).

Exposure of the strains to doxorubicin clearly shows distinct levels of survival to the anthracycline. As shown in Figure 1A, no considerable growth defect is observed between the strains in the absence of the drug. The concentration of doxorubicin used only marginally affects the WT strain but, as expected, is very toxic to the control strains *ssz1* (3% survival) and *ydj1* (3% survival),¹⁶ which corresponds to a 14-fold and 33-fold higher sensitivity to the WT strain ($P < 0.05$) (Figure 1A, B, and Table 2). The SWI/SNF defective strains that displayed the lowest survival were *snf6* (16% survival), *snf2* (10% survival), and *taf14* (4% survival), which correspond to 6.3-fold, 10-fold, and 25-fold higher sensitivity compared to WT (Figure 1B and Table 2). Interestingly, the *taf14* strain showed lower survival to doxorubicin than the positive control *ssz1*. Our data confirm that components of the SWI/SNF complex are necessary for cell viability upon

exposure to doxorubicin, each providing distinct levels of protection. However, some deletion strains did not display significantly reduced survival to doxorubicin, such as *snf11* (59% survival) and *snf5* (76% survival, $P = 0.043$), suggesting they may not play a major role in the response to this agent.

Exposure of the strains to cisplatin revealed that, as with doxorubicin, *snf2* and *taf14* were the most sensitive strains, with a survival of 17%, which constitutes a 5.8-fold higher sensitivity than the WT strain, for both mutants (Figure 2A, B, and Table 2). Among the least sensitive strains, *snf5* displayed $>80\%$ survival. In addition, two other strains presented marginally reduced survival: *snf5* (85% survival, 1.2-fold increase sensitivity relative to WT) and *swp82* (76% survival, 1.3-fold higher sensitivity relative to WT) (Figure 2A, B and Table 2), a behavior that contrasts to their sensitivity to doxorubicin. The positive controls used for this assay were *ssz1* and *ydj1*; these deletion strains behaved as expected, displaying the lowest levels of survival to cisplatin, with 11% survival for *ssz1* (a 9-fold increase in sensitivity relative to WT) and 8% survival for *ydj1* (a 12.5-fold increase in sensitivity relative to WT).

Determination of the sensitivity of SWI/SNF deletion strains to cytotoxic stressors

Doxorubicin and cisplatin exert their antineoplastic activity through multiple mechanisms, including DNA damage by DNA intercalation (doxorubicin) or DNA cross-linking (cisplatin); protein damage by direct binding, or through the generation of reactive oxygen species (ROS), which also damages various cellular structures. To further elucidate the involvement of the SWI/SNF complex in the response to these types of injuries, we determined the sensitivity of the deletion strains to the oxidative stress agent menadione, the DNA-damaging chemotherapeutic agent etoposide, and the protein denaturing effect of heat shock.

Menadione shares the same quinone ring as doxorubicin. This structure generates ROS intracellularly and mimics this property of anthracyclines. As shown in Figure 3A, the strains that displayed the lowest survival were *snf2* (18% survival), *snf6* (21% survival), and *swi3* (30% survival) (Figure 3B), which, respectively, correspond to 5.5-fold, 4.7-fold, and 3.3-fold higher sensitivity to menadione than WT (Table 3). In contrast, the *snf5* and *snf11* strains exhibited no significant change in survival to menadione exposure, with a 130% and 102% survival (76-fold and 98-fold sensitivity relative to WT, respectively). The positive controls *sod1* and *ydj1* are highly sensitive to oxidative

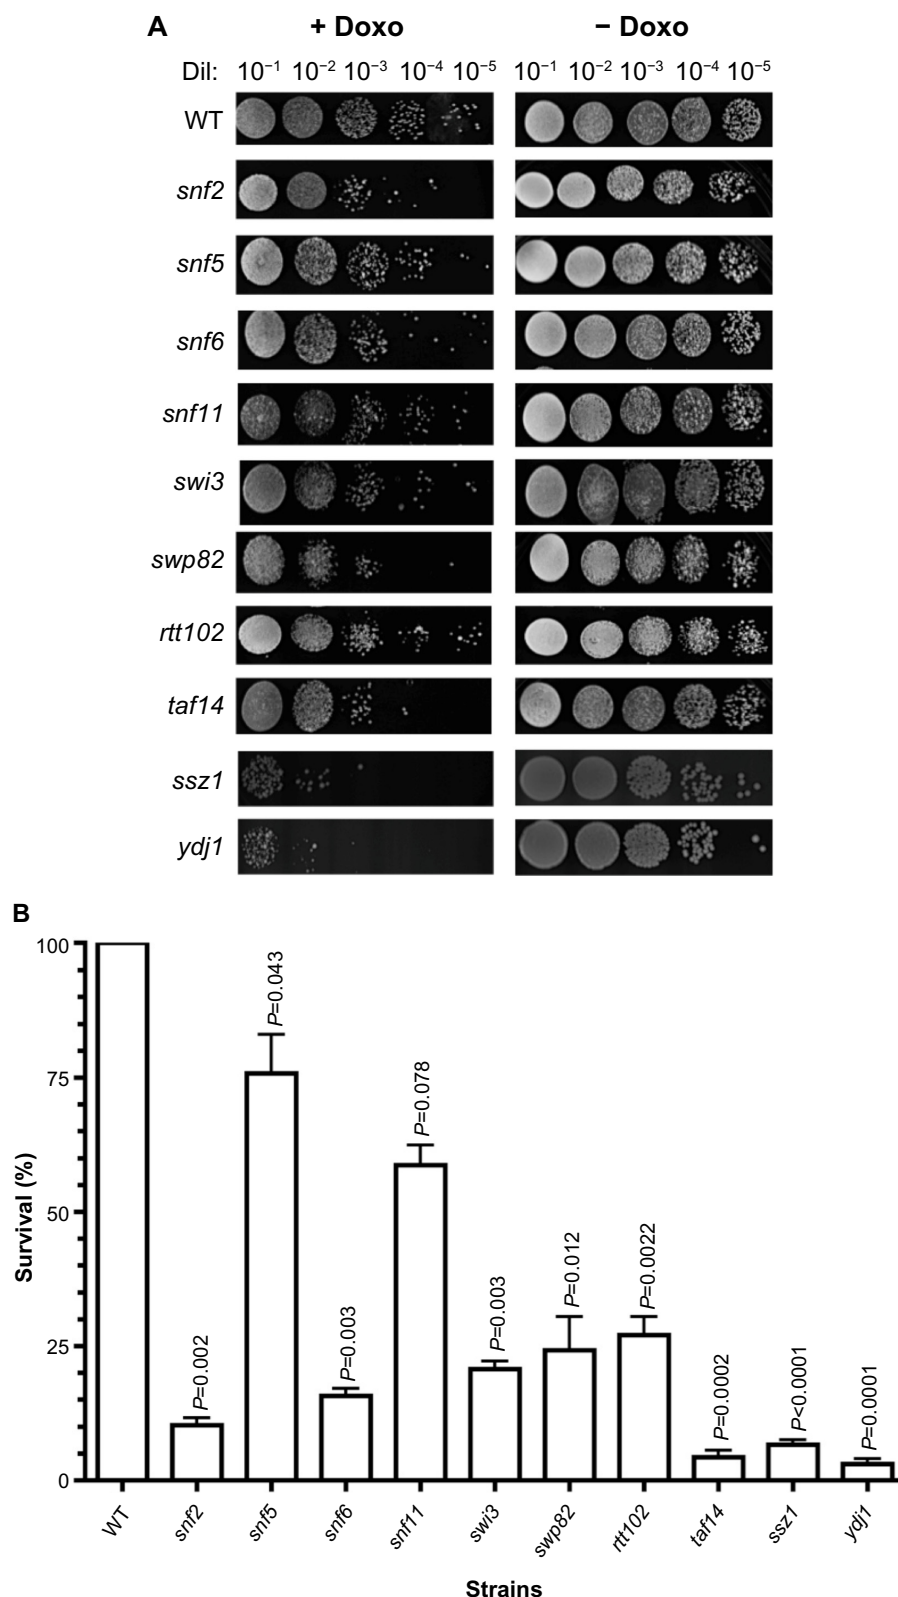

Figure 1 Sensitivity of SWI/SNF deletion strains to chemotherapeutic agent doxorubicin.

Notes: (A) The survival of the strains to 20 $\mu\text{mol/L}$ doxorubicin was determined as described in the “Materials and methods” section. Serial dilutions (1:10–1:10⁵) of the treated cultures were spotted onto YPD plates. Growth was scored after 3 days of incubation at 30°C. The serial dilutions of the strains are shown. Positive controls sensitive to doxorubicin are the *ssz1* and *ydj1* deletion strains. (B) Quantification of the survival of the tested strains. Survival was determined by counting the number of colonies in the respective dilutions and calculated on the basis of the growth of strains not treated with doxorubicin. At least three sets of experiments were used in the statistical analysis. Average survival plus standard deviation is shown. The *P*-values are indicated for each mutant.

stress as expected, with *sod1* displaying 9% survival (11-fold more sensitive than WT). Our assay indicates that some SWI/SNF components are necessary for cell viability when exposed to ROS-generating agents such as menadione.

To test the effect of DNA damage, exclusively, on the SWI/SNF defective strains, we exposed the deletion mutants to the DNA-damaging agent etoposide. This agent, as with doxorubicin, inhibits DNA topoisomerase II, resulting in the

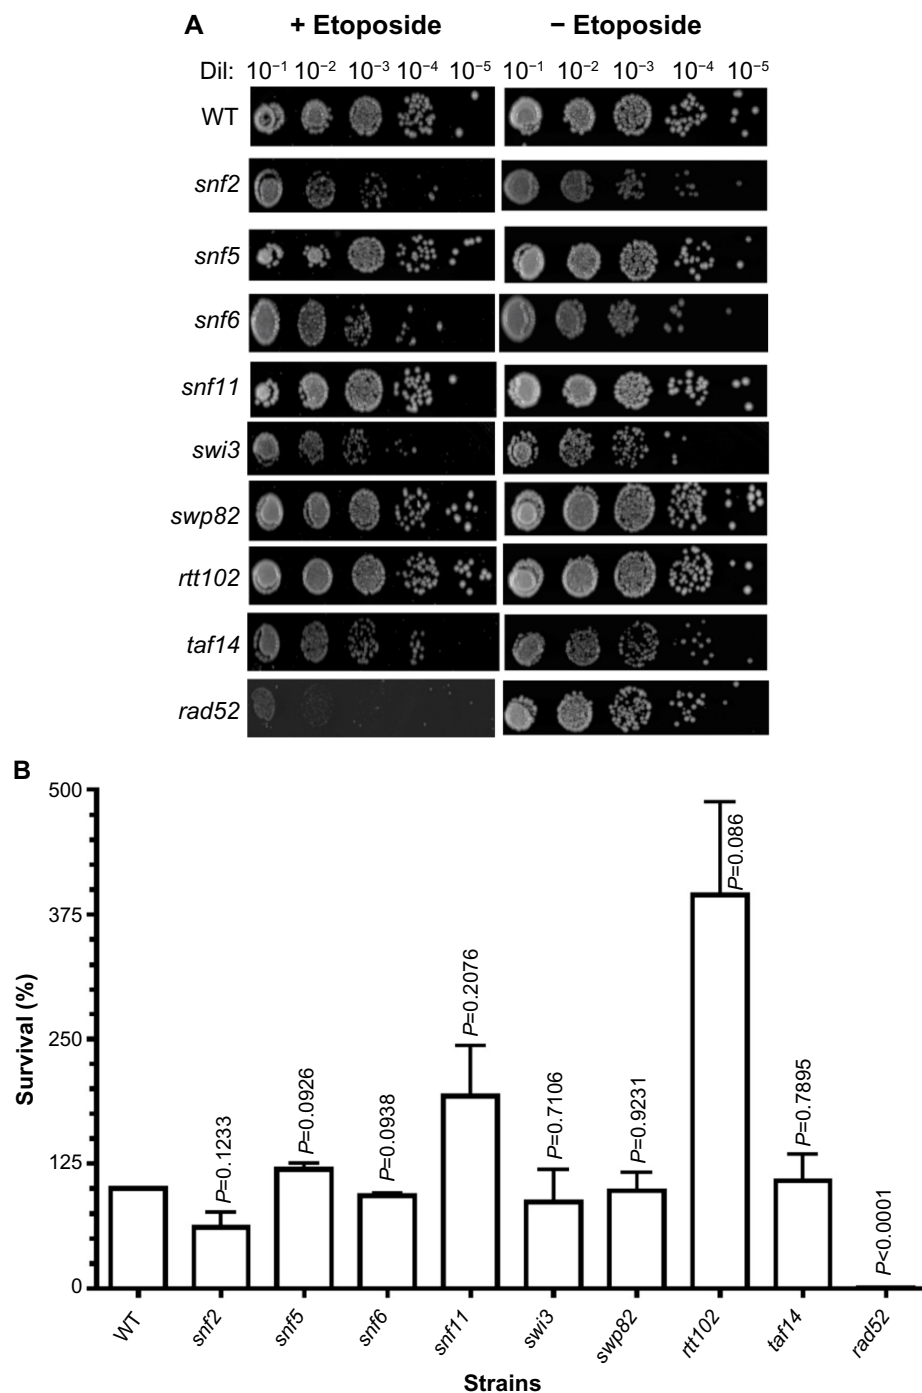

Figure 4 Sensitivity of SWI/SNF deletion strains to etoposide.

Notes: (A) The survival of the strains to etoposide was determined. Serial dilutions of the treated strains were spotted onto YPD agar plates containing etoposide (1 mM) and incubated at 30°C. Growth was scored at 72 hours. Positive controls sensitive to etoposide is the *rad52* deletion strain. (B) Survival was determined by growth of the treated strain relative to the growth of its untreated control. At least three sets of experiments were used in the statistical analysis. Average survival plus standard deviation is shown. **Abbreviations:** YPD, yeast extract/peptone/dextrose; WT, wild type; Dil, serial dilutions.

accumulation of DNA double-strand breaks. When exposed to etoposide (1 mM), the majority of the SWI/SNF mutants did not display significantly reduced survival. At this drug concentration, the positive control *rad52* is highly sensitive, with a survival of 0.38% (267-fold higher sensitivity than WT). However, the most doxorubicin-sensitive strains, *snf2*, *snf6*,

swi3, and *taf14*, showed survival of 61%, 93%, 87%, and 108%, respectively, with *P*-values indicating that they are not significantly different from the WT strain (Figure 4A, B and Table 3). Furthermore, the *rtt102* mutants (Figure 4A and B) displayed increased survival to etoposide, with a 394% survival (3.9-fold more resistant than WT; Table 3).

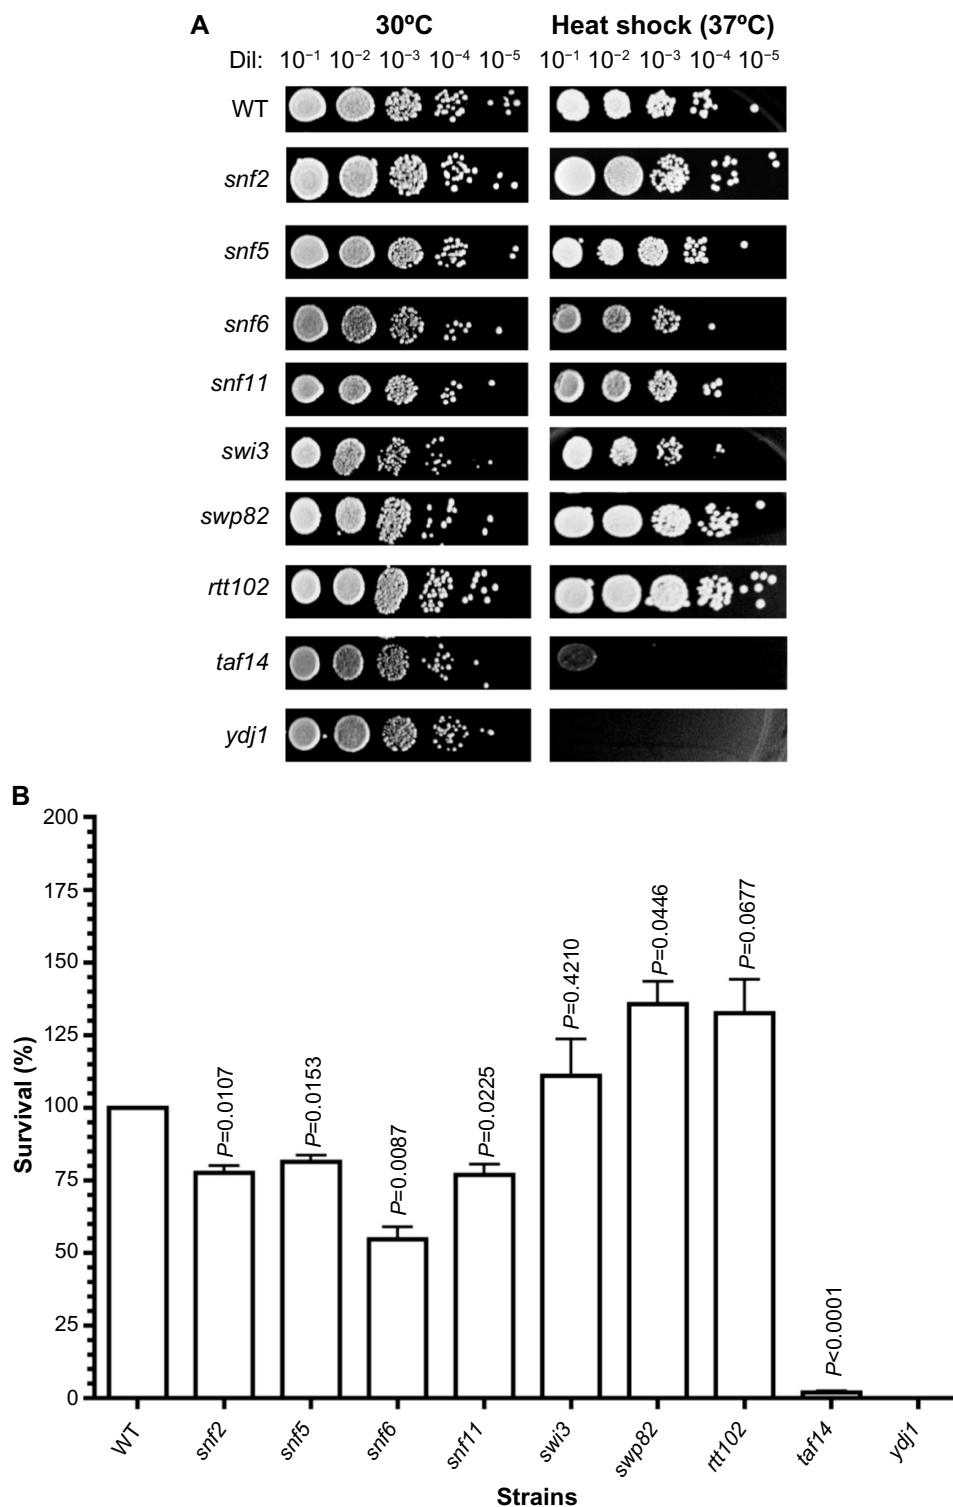

Figure 5 Sensitivity of SWI/SNF deletion strains to heat shock.

Notes: (A) SWI/SNF deletion strains were tested for heat sensitivity. Serial dilutions of the cells were plated onto YPD agar plates and incubated at 30°C (untreated controls) and at 37°C (heat shock). Growth was scored at 72 hours. Positive controls sensitive to heat shock is the *ydj1* deletion strain. (B) Survival was determined by growth of the heat-shocked strain relative to the growth of non-heat-shocked cells. At least three sets of experiments were used in the statistical analysis. Average survival plus standard deviation is shown.

Abbreviations: YPD, yeast extract/peptone/dextrose; WT, wild type; Dil, serial dilutions.

In thermotherapy, elevated body temperature can be an effective adjunct therapy when used with chemotherapy or radiotherapy in combating cancer.¹⁹ To investigate whether inactivation of SWI/SNF factors hypersensitizes cells to

hyperthermia, we determined the viability of the deletion mutants to heat shock. The positive control *ydj1* strain, which is defective in a heat-shock protein 40 (HSP40) and is essential in the heat-shock response, is highly sensitive to growth at

high temperature. Among the SWI/SNF mutants, the *snf6* and *taf14* strains (Figure 5A) displayed the lowest survival, with 54% and 2% (which is 2-fold and 50-fold more sensitive than WT; Figure 5B and Table 3), respectively. Conversely, the *swp82*, *swi3*, and *rtt102* strains (Figure 5A) exhibited the least sensitivity to heat shock, with 136%, 111%, and 133% survival, respectively (Figure 5B and Table 3).

Discussion

Cytotoxic cancer treatment is often associated with side effects and the potential development of drug resistance. However, frequently, the limited number of biological targets leaves traditional cytotoxic chemotherapy as the only therapeutic alternative. For example, patients affected by triple negative breast cancer are presently treated with single-agent or combination therapies including doxorubicin, cisplatin,

epirubicin, 5-fluorouracil, paclitaxel, cyclophosphamide, methotrexate, and gemcitabine.^{20,21} While effective, most of these chemotherapeutic agents are associated with serious side effects, such as cardiotoxicity, neutropenia, neuropathy, and persistent metastatic tumor progression.^{20,22} Current attempts to treat with options involving less toxicity yield a much poorer total response.^{23,24} Consequently, there is a need to enhance the therapeutic efficacy as well as to reduce toxic side effects.

Increasing the efficacy of chemotherapy may be achieved by hypersensitizing the cancer cells to the treatment. Sensitization may allow for the use of lower dose therapy to attain comparable response, concomitantly decreasing the risk of dose-dependent adverse effects.

Previous work from our laboratory¹⁶ identified a deletion of the *SNF2* gene which hypersensitizes cells to doxorubicin, suggesting that the SWI/SNF chromatin remodeling complex can serve as a novel target for cell sensitization to cytotoxic chemotherapy. We extended this observation by investigating the role of other SWI/SNF complex components in the response of cells to therapeutic agents, such as doxorubicin, cisplatin, and etoposide, and to defined cytotoxic stresses such as ROS and heat shock.

We tested all the nonessential mutants of the SWI/SNF complex (Table 1) to determine which deletion strains exhibited higher sensitivity in response to various forms of cytotoxic stress. Two deletion mutants, *snf2* and *taf14*, were found to be consistently hypersensitive to all agents, except for heat shock which only significantly affected the *taf14* strain.

Among the chemotherapeutic agents evaluated, doxorubicin was the most effective one, with the majority of the

Notes: *The *ydj1* strain, which serves as the sensitive control for heat shock, is unviable at 37°C. The sensitivity is then estimated based on the higher serial dilution (1:10⁵) to be at least >10⁵-fold higher than the wild-type strain.

Abbreviation: SEM, standard error of the mean.

mutants displaying significant sensitivity relative to the WT strain. It is worth emphasizing that the concentration of the drugs used was selected to identify hypersensitive strains. Increasing the dose will eventually kill all strains, including the WT, and would not allow us to discriminate the hypersensitive strains from those unaffected. While *snf2* and *taf14* were hypersensitive, *snf6*, *swi3*, and *swp82* displayed intermediate sensitivity and *snf5*, *snf11*, and *rtt102* displayed different levels of resistance, depending on the agent. The *snf5* mutant was not affected by doxorubicin, cisplatin, or etoposide, and was resistant to menadione. Similarly, the *snf11* mutant was resistant to etoposide and menadione, and the *rtt102* strain was highly resistant to etoposide. Proper controls were included in each experiment, with well-known hypersensitive strains, to confirm the effectiveness of the dose used.

The distinctive mechanisms of our chemotherapeutic agents may contribute to each SWI/SNF factor's ability to protect the cell from incurring cytotoxic damage. Direct DNA damage was induced with cisplatin, which forms adducts on DNA leading to cross-linking.²⁵ Doxorubicin has multiple cytotoxic mechanisms, including DNA damage by intercalation¹⁵ as well as the generation of free radicals¹⁵ that damage various cellular structures. To determine the mechanisms of the chemotherapeutic drugs responsible for causing the cytotoxicity in the SWI/SNF mutant strains, we selected single-action agents, such as the DNA-damaging agent etoposide, which, like doxorubicin, also inhibits DNA topoisomerase II; menadione, which generates oxidative stress; and the protein denaturing property of direct heat shock.

Interestingly, while the majority of the strains were sensitive to doxorubicin, none of them, except for *snf2*,

was sensitive to etoposide and only partially mimicked the response when exposed to oxidative stress induced by menadione. These results suggest that anthracycline's oxidative stress and DNA damage synergize to kill the cells.

The diverse response of the deletion strains tested may be explained by their specific interactions with distinct factors. Among the most interesting genes from our study are those that, when deleted, lead either to hypersensitivity: *snf2*, *taf14*, *swp82*; or to resistance: *snf5*, to any particular agent.

The SNF2 protein has several roles in transcriptional regulation, facilitated by its interactions with over 140 genes.²⁶ It is required for adenosine triphosphate (ATP) hydrolysis and the conversion of the energy to power ATP-dependent chromatin remodeling, maintaining the structural integrity of the SWI/SNF complex,²⁷ and essential for both telomere and ribosomal DNA silencing.²⁸ The *SNF2* gene has also been found to genetically interact with the DNA repair gene *RAD26*²⁹ as well as the heat-shock gene *HSP82*. Interestingly, *HSP82* interacts with *SNF2*, within a network of genes also interacting with *SIN4*, *TUP1*, *SMT3*, *UBI4*, *SPT15*, and *SNF11*.

TAF14 is a component of the *yaf9*, *taf14*, and *sas5* YEATS domain in *S. cerevisiae*, which in humans includes proteins involved in acute leukemia. The YEATS domain family is essential, as a *yaf9*, *taf14*, *sas5* triple mutant is nonviable.³⁰ The *YAF9* gene, which *TAF14* interacts with, has been found to be required for the proper gene expression and histone acetylation near telomeres. The *TAF14* gene also shows extensive genetic and physical interactions with RNA polymerase factors and TATA-binding protein-associated factors. Proper function of *Taf14* is essential for RNA polymerase II transcription initiation and chromatin modification.

The Snf5 protein, which is encoded for by the *SNF5* gene, is involved in the downregulation of transcriptional gene silencing (prevention of gene expression) through interactions with histone H2A and H2B³¹ proteins that are needed for the assembly of chromatin and the proper function of chromosomes. The *SNF5* gene interacts with every factor of the SWI/SNF complex.²⁶

The biological process of Swp82, as well as its molecular function, remains unknown. *SWP82* interacts with 34 genes, including histones, ubiquitin protease, transcription factors, and the other subunits of the SWI/SNF complex.²⁶

Several of the SWI/SNF genes that display sensitivity to our induced cytotoxic stress, such as *SNF2*, *SWI3*, and *SNF5*, have human homologues *BRG1* or *hBRM*, *BAF155*, *BAF170*, and *SNF5/INI1* or *BAF47*, respectively. The potential targeting of these factors to hypersensitize cancer cells to chemotherapy is an attractive possibility and has support from a recent study which showed that BRCA1 CpG island promoter hyper-methylation-associated silencing predicts enhanced sensitivity to platinum-derived drugs such as cisplatin.³²

While subunits of the SWI/SNF complex may be mutated in human cancers, only the *SNF5/INI1* (*BAF47*) subunit of the mammalian SWI/SNF complex, a homologue of *S. cerevisiae* SNF5,³³ has been shown to function as a tumor suppressor.³⁴ A recent report correlating the expression levels of the SWI/SNF factor with cancer prognosis suggests that other components of the complex may, as well, act as tumor suppressors.³⁵

Considering the direct role of the SWI/SNF complex in the assembly of nucleosomes, alterations in the composition of the complex may play a significant role in the expression of genes directly involved in the sensitivity to drugs. Reorganization of nucleosomes may occur in the mutant strains, which alters expression of genes, concomitantly affecting drug resistance. In fact, a recent report describes the reactivation of drug resistance by reassembly of nucleosomes at sites that block expression of *MLH1*.³⁶ It would be interesting to determine the expression differences between the SWI/SNF mutant strains to determine the genes involved in the cellular response to cytotoxic drugs, and correlate these expression changes with nucleosome repositioning in the genome in these strains.

Additional research will elucidate the role of these genes in mammalian cells as a required step to consider these genes and/or the pathways they participate in as potential drug-gable targets that can be used to enhance chemotherapeutic treatment.

Acknowledgments

We are grateful for the support provided by the Gene and Cell Manipulation Facility, Florida A&M University. This project was supported by the National Center for Research Resources and the National Institute of Minority Health and Health Disparities of the National Institutes of Health through grant numbers 2 G12 RR003020 and 8 G12 MD007582-28.

Biologics: Targets & Therapy

Publish your work in this journal

Biologics: Targets & Therapy is an international, peer-reviewed journal focusing on the patho-physiological rationale for and clinical application of Biologic agents in the management of autoimmune diseases, cancers or other pathologies where a molecular target can be identified. This journal is indexed on PubMed Central, CAS, EMBase, Scopus

Submit your manuscript here: <http://www.dovepress.com/biologics-targets--therapy-journal>

Dovepress

and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
