Abstract: A combination of a Wilms' tumor (WT) and renal cell carcinoma (RCC) is an extremely rare pediatric renal neoplasm. Its prognosis and clinicopathological features remain unclarified. Herein, we describe a case of the coexistence of a WT and an RCC in a male child aged 5 years and 10 months. The child had symptoms of hematuria for more than 1 month. Although his irises were clear, medical imaging revealed a potential malignant tumor in the left kidney. The patient underwent resection of the left kidney. The pathological diagnosis was the coexistence of a WT and papillary RCC. Negative surgical margins were examined. One month following the resection, chemotherapy with vincristine plus dactinomycin (EE-4A regimen) was commenced. At the 69-month follow-up, there was no recurrence or metastasis. The coexistence of a WT and an RCC in the pediatric population is considered a rare pathological event. At present, there is no standard treatment for these renal neoplasms. In this study, the RCC treatment, which was the same as that applied in cases of WTs, was reasonable.

Keywords: papillary renal cell carcinoma, coexistence, renal cell carcinoma, nephroblastoma

Introduction

A Wilms' tumor (WT) remains one of the most frequently detected kidney malignancies in infants and young children, with a higher morbidity rate among those aged 3–4 years.^{1,2} WTs are widely regarded as embryonal tumors, which stem from metanephrogenic blastema.³ A renal cell carcinoma (RCC) is a rare malignancy in children. Unlike WTs, most pediatric cases of RCCs are diagnosed in the second decade of life, and the possibility of morbidity increases with age.⁴ In most adults, the histological type is a clear cell RCC, whereas the histological subtypes of RCCs in children tend to be microphthalmia transcription factor translocation RCCs and papillary RCCs.^{1,5} To the best of our knowledge, the coexistence of a WT and an RCC is rare, with only a few cases reported in the literature.^{6–9} In this paper, we describe a case of the coexistence of a WT and an RCC, together with the clinicopathological features, treatment, and prognosis. In addition, a literature review of relevant studies was conducted with the aim of improving our understanding of this rare disease.

Case report

A boy aged 5 years and 10 months was admitted to the hospital on 13 October 2012 with recurring symptoms of hematuria for more than 1 month and weight loss of 1 kg. No urinary irritation symptoms, chills, fever, or rashes were observed. In the neonatal period, the boy had been well nourished. A physical examination revealed

Figure 1 A computed tomography image, with intravenous contrast.
Note: The mass in the left renal middle pole is shown (white arrows).

no enlargement of the tongue, umbilical hernia, iris loss, genitourinary malformation, or mental dysplasia. The kidneys did not seem to be swollen, and there appeared to be no pain when percussed or pressed. Similarly, pressing on the bladder area induced no pain, and no mass was found. There was no family history of nephroblastomas.

Blood and liver function tests revealed no obvious abnormalities. However, a routine urine test showed proteinuria and hematuria. A computed tomography (CT) scan revealed a 2.9 cm in diameter shadow of round, soft tissue in the mid pole of the left kidney, with an uneven density. Scattered calcifications were also detected (Figure 1). Color ultrasound imaging confirmed the presence of a hyperechoic mass (2.2×1.5 cm) in the mid pole of the kidney, with an intense blood signal (Figure 2). Emission computed tomography (ECT) pointed to the presence of space-occupying lesions in the left kidney, in which the blood supply was increased, suggesting a malignant tumor.

The patient underwent resection of the tumor on 22 October 2012. In the process of the resection, the tumor was seen to be located in the mid pole of the left kidney. The papillary tumor invaded the renal parenchyma and pelvis, but the kidney capsule and ureter were tumor free. Further, lymphadenectomy was not found surrounding the renal pedicle.

Gross examination showed a grayish-white irregular 2.5×2.5×2 cm sized mass in the left kidney, with a definite boundary. The surface of the mass was partly adhered to the kidney capsule. The cut surface showed that the tumor had spread from the renal cortex to the medulla and finally to the renal pelvis, with formation of several cysts. Some large cysts included grayish yellow papillary excrescences (Figure 3). Under a microscope, the tumor consisted of a papillary RCC and WT. The papillary RCC was located in the cyst, and the cancer cells were arranged in a papillary shape. The thin fibrovascular cores could be observed in these papillae, and some of the tumor tissue invaded the cyst wall (Figure 4A–C). The majority of the WT tissue was epithelium, and well-differentiated tiny tubes coexisted with poorly differentiated original tubular structures (Figure 4D and E). Loose connective tissues (Figure 4A) and immature mesenchymal tissues were discovered between the WT and papillary RCC (Figure 4F). The surgical margins were clear. As shown by immunohistochemical staining, the papillary RCC region was positive for cytokeratin 7 (CK7), alpha-methylacyl coenzyme A racemase, and cluster of differentiation 10 but negative for Wilms tumor gene 1 (WT1). The immunoprofile of WT region was contrary to the former (Figure 5). The pathological diagnosis was an epithelial WT coexisting with a papillary RCC in the left kidney.

According to the criteria of the National Wilms' Tumor Study, the WT was classified as Stage I. Based on the pathological grading, the RCC was classified as Grade 2,

Figure 2 Color ultrasound images of the space-occupying lesion in the left kidney.

Notes: (A) A hyperechoic mass was detected in the mid pole of the left kidney, with a definite boundary and an irregular shape. (B) A rod-like blood signal was detected in the mass, and renal perfusion was normal.

Figure 3 Macroscopic appearances.

Notes: Gross examination of the left kidney showed that (A) the tumor was located in the mid pole of the kidney, with observable solid and cystic areas. (B) The surface of the cystic areas had tiny papillary excrescences (red arrows), and the solid area seemed grayish white (black arrows).

Figure 4 Histomorphological features.

Notes: (A) The tumor was composed of a papillary RCC and WT, with fibrous connective tissues between the fibers (magnification, $\times 40$). (B) The RCC area was arranged in a papillary shape, and the thin fibrovascular cores could be observed. The papillary surface was covered with a monolayer or pseudostratified columnar cancer cells (magnification, $\times 400$). (C) Psammoma bodies were detected in the stroma (magnification, $\times 400$). (D) The WT was mainly composed of epithelium, and the original tubular structure and well-differentiated tubules were visible under a microscope (magnification, $\times 100$). (E) Under a high-magnification microscope, the well-differentiated tubules were made up of columnar epithelial cells, with long and thin wedge-shaped nuclei (magnification, $\times 400$). (F) The stroma consisted of immature fusiform-shaped cells, with slightly basophilic mesenchyme. A small number of eosinophil cells were scattered between the juvenile fusiform cells (magnification, $\times 400$).

Abbreviations: RCC, renal cell carcinoma; WT, Wilms' tumor.

Figure 5 Immunohistochemistry.

Notes: (A) Cytokeratin 7 was strongly positively expressed in the cytoplasm of the papillary RCC cells (magnification, $\times 400$). (B) Alpha-methylacyl coenzyme A racemase displayed weak positive expression in the cytoplasm of papillary RCC cells (magnification, $\times 400$). (C) Cluster of differentiation 10 was slightly positively expressed in the papillary RCC cells (magnification, $\times 400$). (D) WT1 exhibited strong positive expression in the WT nuclei (magnification, $\times 400$).

Abbreviations: RCC, renal cell carcinoma; WT, Wilms' tumor; WT1, Wilms tumor gene 1.

and the TNM staging was T1aN0M0. Therefore, the treatment provided was in accordance with that for a Stage I WT (ie, radical nephrectomy of the left kidney, with complete resection of the tumor). After the operation, the patient recovered quickly. One month after the operation, the patient received vincristine plus dactinomycin (EE-4A regimen) as chemotherapy and underwent regular CT and B-mode ultrasound examinations. At the 69-month follow-up, there was no recurrence or metastasis.

This study was approved by the medical ethics committee of the First Affiliated Hospital of Guangxi Medical University. Written informed consent has been provided by the legal guardian of the patient to have the case details and any accompanying images published.

Discussion

The coexistence of a WT and an RCC is an extremely rare medical situation, with only nine similar cases published in the English literature (Table 1). These cases comprised five boys and four girls aged 1–14 years, with the average age being 4.8 years and median age being 3 years.^{6–9} The age of the patient in the present study with a WT coexisting with

an RCC was 5 years and 10 months, which was consistent with the age of onset reported in the literature.

The clinical features of a WT coexisting with an RCC are not specific and can be manifested as hematuria, fever, and an abdominal mass.⁹ Medical imaging aids the preoperative diagnosis, staging, and postoperative monitoring of renal tumors in children.^{3,10–12} In the present case, the patient had recurring hematuria and weight loss. A CT examination revealed a mass with an uneven density and scattered calcifications, which could aid the diagnosis of RCCs.^{13,14} Both color ultrasound and ECT showed increased vascularity and intense blood signals, indicating the possibility of a malignant tumor.

Prior to surgery, it is difficult to diagnose the coexistence of WTs and RCCs in children, and the diagnosis mainly depends on histology and immunohistochemical staining. A WT is composed of blastema, epithelium, and stromal. Pathologically, a WT is categorized into two types: a favorable histological type and an unfavorable histological type.^{15–17} In the present case, the WT largely consisted of epithelium, with little mesenchyme and no blastema. The gross examination showed few differences as compared

with observations of other tumors, including pediatric RCCs, which are generally characterized by a small size, solid mass, necrosis, hemorrhages, and cystic changes.¹ It also revealed several papillary excrescences in some large cysts. These were later confirmed as structures of the papillary RCC in the microscopic analysis. Occasionally, papillary RCCs exhibit similarities to epithelial WTs with papillary structures.⁵ In the present case, positive immunohistochemical staining of CK7 served as a marker of the papillary RCC. The area of the papillary RCC showed positive expression of CK7 and negative expression of WT1, which validated the diagnosis.

The existence of a biological relationship between RCCs and WTs has not been confirmed. However, since the first report of WT, many studies have discovered RCCs secondary to WTs.^{18–20} In a review article, the authors found that WT patients had a genetic predisposition to tumor formation, whereas others revealed that secondary RCCs were associated with radiotherapy and chemotherapy.¹⁸ In the present case, the WT and RCC were of a similar size, and the two tumors were separated by fibrous tissues, with no direct connection or transitions.

Due to their infrequency and short follow-up periods, the prognosis in cases of the coexistence of WTs and RCCs remains unclear. In patients with WTs, the overall survival rate was over 90%, and factors associated with a poor prognosis included an anaplastic type, more advanced stage, and loss of heterozygosity (LOH) for chromosomes 1p and 16q.^{15,21} The treatment for WTs is multidisciplinary and involves surgery and chemotherapy, which is individualized based on risk stratification.¹⁵ Biological markers associated with a poor WT prognosis include LOH at 1p/16q, LOH at 11q, LOH at 4p and 14q, 1q gain, *MYCN* amplification, and *TP53* and *WT1* mutations.^{21,22} The prognosis of RCCs

in children is poorer than that in WT cases, with an overall survival rate of 64%. The tumor stage plays a vital role in the overall survival rate.¹ In patients with RCCs insensitive to chemotherapy and radiotherapy, the appropriate treatment is radical nephrectomy, with complete resection of the tumor.²³ In a previous study, the researchers suggested that the treatment applied in cases of WTs could also be applied in cases of WTs coexisting with RCCs, regardless of the size of each tumor.⁹ In the present case, the WT was the favorable histological type, and it was classified as Stage I according to the National Wilms' Tumor Study criteria. The RCC was categorized as histological Grade 2, and the TNM stage was T1aN0M0. The patient was treated with radical nephrectomy, with complete resection of the tumors, in combination with chemotherapy and postsurgery. Regular medical imaging and the findings at a 69-month follow-up showed no recurrence of the tumors.

Conclusion

The coexistence of a WT and an RCC is a rare occurrence in children, and it is difficult to diagnose the coexistence of these tumors before surgery. The diagnosis of a WT coexisting with an RCC may be determined by histopathology and immunohistochemistry. No standard treatment is available owing to the infrequency of these renal neoplasms. The treatment for a WT seems appropriate in cases of a WT coexisting with an RCC.
