**Background:** China is one of the countries sharing the major burden of tuberculosis (TB) in the world. Health care workers (HCWs) are subject to a high risk of occupational latent tuberculosis infection (LTBI)—an asymptomatic state of TB disease. However, the heterogenic composition of healthcare professionals in terms of nature of their work leads to the inconsistency in predicting the prevalence of LTBI amongst them. Furthermore, the global statistics do not account for the analysis conducted within the Chinese population. Our study reflects a systemic and epidemiological meta-analysis to investigate the risk of contracting LTBI by the HCWs of China.

**Methods:** A systematic review of the literature was performed to identify studies reporting LTBI prevalence or incidence among HCWs and a control groups in China. Risk of infection, as well as subgroup analysis was calculated by pooled effect estimates. Review Manager 5.0 was used to perform the meta-analyses.

**Results:** Twenty studies containing 9,654 HCWs met the inclusion criteria. The average prevalence of LTBI among HCWs was 51.5%, ranging from 27.9–88.8%. HCWs had a higher risk of prevalence of LTBI than the control groups [odds ratio (OR), 1.78, 95% confidence interval (CI), 1.46–2.16]. In the subgroup analysis, the prevalence of LTBI in HCWs with respect to the control groups was observed to be highest in Eastern China (OR, 2.05; 95% CI, 1.35–3.11). Furthermore, the pooled OR for LTBI was 1.90 and 1.65 separately from the results of the tuberculin skin test (TST) and the interferon-gamma release assay. Lastly, upon comparing the HCWs with the control groups from the community and the nosocomial source, it was observed that the pooled OR favored for the prevalence of LTBI, which was primarily community-sourced (3.12 and 1.54). HCWs had an increased risk of prevalence of LTBI than the control groups, both in general hospitals and TB specific hospitals (pooled OR 2.4 and 1.57).

**Conclusions:** Risk of LTBI infection among HCWs is relatively high in China, especially in the eastern region, predisposed by the cumulative exposure to *Mycobacterium tuberculosis* from the community and the general hospitals. Overall, our data reflects an alarming risk posed to our HCWs, and calls for immediate reforms at the policy levels, so as to implement effective screening and treatment of affected HCWs in China.

## Introduction

The global burden of tuberculosis (TB) on healthcare is tremendous. TB ranks as one of the top 10 causes of mortality worldwide, even surpassing HIV/AIDS. As per the 2017 statistics, China accounted for 9% of the global population that developed TB disease, ranking second only to India (1-3). While TB typically affects the lungs, the state of host immune response determines the symptoms of this disease. The symptoms range from a stage of clinical latency, wherein the host immune response is able to keep a check on the pathogen, to an active TB, wherein the bacteria, *Mycobacterium tuberculosis*, overpowers the host immune cells (4). Latent tuberculosis infection (LTBI) is the former state that carries a dynamic balance between bacteria and the host. It is characterized by a persistent biologically positive, immune controlled stage with no clinical evidence of TB. However, the body cannot completely eliminate the pathogen from its system (5). Worldwide, nearly one-third of the global population is estimated to have LTBI (1), while in China, it ranges from 13% to 40% (6). Although only about 5–10% of LTBI cases will progress to active TB, as seen during the follow-ups (3-5), its detrimental effects on our population and healthcare systems cannot be undermined.

A study based on the longitudinal predictive model in China suggested that smear-positive patients were the main sources of new infections of TB at present, but the second related trend was the platform phase lasting for nearly 50 years. This persistence was likely to due to the remaining cases of LTBI (13–20%), and a fairly high rate of conversion from LTBI to active TB (5–10%) (7).

Health care workers (HCWs) are defined as people engaged in professions aimed at enhancing the well-being of individuals. While at work, they are commonly exposed to TB patients who may spread the infection in the hospitals even before their diagnosis is confirmed (8). It is thus, imperative to consider systematic testing and treatment of HCWs for LTBI (5). Unfortunately, LTBI testing is not widely available for HCWs (9). Until 2018, HCWs screening was often overlooked especially in low- and middle-income settings and countries (5,10). The lack of data of LTBI prevalence has further aggravated the problem. The current study attempts to analyze the risk faced by HCWs in contracting LTBI, in China.

An earlier study considered two heterogeneous groups of HCWs wherein one-third (19.8 million) included administration and support workers, while the other two thirds (39.5 million) comprised of the frontline workers

directly involved in providing medical treatment to the patients (9). Inconsistent conclusions among different studies were found, primarily due to the heterogeneity associated with the sampling. The risk of TB among HCWs was reported to be controversial as some studies focused on the administration groups that have no direct contacts with the TB patients, whereas others focused on the occupational groups that posed an increased risk (11). Another major factor to gauge is that whether the high risk of LTBI in HCWs is acquired from the community or the occupation (12-14). It is notable, that in low TB risk settings and countries (13) such as USA (12), Germany (14) and Iran (15), LTBI amongst HCWs primarily seems to be sourced from the community. However, the high TB risk settings and countries (16) exhibit risk derived primarily from the occupation.

Given the high probability that LTBI is likely to develop into active TB, this meta-analysis aims to investigate the epidemiology and burden of LTBI in Chinese HCWs. Moreover, we also follow with interest the administration groups as our internal control to analyze whether the higher risk of LTBI in HCWs is community acquired or is occupational. We also surveyed if the risk remains same across different kinds of hospitals in China, i.e., general hospitals versus TB specialized hospitals.

## Methods

Preferred Reporting Items for Systematic Reviews and Meta-Analyses: The PRISMA Statement was used as guideline in this meta-analysis (17).

### *Literature search strategy*

Our search strategy seeks to identify all the accessible studies without any date or language restrictions, which reported data on the prevalence and incidence of LTBI disease among HCWs in China. We searched English databases including PubMed, Web of Science, EMBASE (Ovid), Wiley online Library, Cochrane library, the last of which was to confirm that no similar meta-analysis nor reviews have been published, so far in the given context. Chinese language articles without full text were excluded from these databases and were identified in Chinese database. Considering that a majority of studies include both TB and LTBI, we searched for studies on both subjects and then excluded the ones based exclusively on TB, in the last step. Literature published in Chinese was also obtained

from CNKI ([www.cnki.net](http://www.cnki.net)), Wanfang ([www.wanfangdata.com.cn](http://www.wanfangdata.com.cn)), VIP ([www.cqvip.com](http://www.cqvip.com)) and CBM database ([www.sinomed.ac.cn](http://www.sinomed.ac.cn)). The Venn Diagrams of Chinese and English databases were performed in [Figures S1](#) and [S2](#), respectively. Search strategy has been summarized in [Table S1](#). In addition to the above databases, we also searched for reference lists of review articles, primary studies and textbook chapters with relevant research data. We also hand searched the indices of the *International Journal of Tuberculosis and Lung Disease*, *Tuberculosis and Tubercle & Lung Disease* for relevant articles not captured by the electronic searches. In general, keywords such as “tuberculosis”, “health care workers” and “China” were used for searching the relevant articles. As an illustration, we used Medical Subject Headings (MeSH) in Pubmed database first. Secondly, the terminology “*Mycobacterium tuberculosis*” was substituted by the key word “tuberculosis” to enrich our search results. Other terminologies such as “health care personnel”, “health worker”, “healthcare professional”, “allied health personnel”, “medical staff”, “hospital staff”, “physicians”, “nurses”, “community health worker” were substituted for “health care workers”. Next, we used both the key words and subjects recognized in the databases with the operator “OR” for each terminology in each database. Finally, the keywords and subjects for each terminology were combined with an “AND” operator to obtain the final search result. This work considered data published up to September 30<sup>th</sup> 2019.

### ***Inclusion and exclusion criteria***

Literature references focusing only on the prevalence of LTBI were considered. Case-control studies, cross sectional LTBI surveys, cross-sectional cohort studies in the prevalence of LTBI among HCWs were included.

Either a tuberculin skin test (TST) or interferon-gamma release assay (IGRA) was used to confirm the presence of LTBI (5). HCWs were grouped according to the type of hospitals they were associated with, namely, the TB hospitals and the general hospitals. TB hospitals are classified as ones that have the facilities to diagnose and treat TB subjects, while general hospitals are characterized as the first to the third trinity community and country hospitals without any special TB departments. Control groups were defined as: (I) any of the administrative, finance or library staff within the studies, (II) comparable groups of non-HCWs and as per (III) the studies indicating the accurate source of the control data from national resource or elsewhere.

We excluded conference abstracts, letters and comments that did not allow extraction of relevant data, reviews as well as case reports or case series of nosocomial transmission or outbreaks. The latter is considered to be an inherently exceptional situation that may interfere in estimating the true prevalence, incidence and risk factors contributing to nosocomial transmission (13). We also excluded studies that utilized questionnaire responses to ascertain prevalence of LTBI. Inaccurate source of the control data or estimates taken from other studies, studies with ambiguous data analysis were also excluded. When the same population was studied in different papers, the most recent one or with highest quality was included.

Studies that aimed to compare LTBI in the TB associated comorbidities groups and the non-comorbidities groups were not included, primarily because comorbidities like diabetes, human immunodeficiency virus (HIV), chronic kidney disease and malignant tumor increase the risk of infection in TB populations (18). If HCWs and non-HCWs populations were later found to include these comorbidities then in that case they were not excluded.

### ***Data extraction and outcomes of interest***

These data from a subset of eligible studies were extracted independently by two reviewers (Guo and Zhong) using a standardized data extraction form. Any disagreement was resolved by the adjudicating senior authors (Wu and Qiu). Data extracted included: date of publication, author, province of study, year of study, study design, sampling method, type of HCWs, source of control group, methods that used to test for LTBI (TST or IGRA). For the prevalence and incidence studies, the following procedure was employed to standardize the data-extraction process. Data from the LTBI prevalence studies was extracted including the number of HCWs and control groups, and the associated number of positive TST or IGRA cases in HCWs and control groups, respectively. If the study conducted a series of screening methods, only the first data was considered, as subsequent screening often leads to skewness of data towards the increased risk associated with occupation. We also conducted subgroup analysis and divided China into the western, central, and eastern regions according to national geographic data (19).

### ***Quality assessment and statistical analysis***

Based on the literature database that we compiled, we investigated the study designs of only the cross-sectional

**Figure 1** Flow diagram of studies identified, included, and excluded.

studies. The scale of Agency for Healthcare Research and Quality (AHRQ) provided by the US Health Care Quality And Research Institutions was used to evaluate the study quality. It contained 11 item/parameters where in the response for each item- is either “yes”, “no” or “unclear” (20). For our meta-analysis, we considered all the studies, however, during the subgroup analysis we dropped the studies that exhibited low data quality.

Review Manager 5.0 (Cochrane Collaboration, Oxford, UK) was used to perform the meta-analyses. For studies investigating the prevalence of LTBI, odds ratios (ORs) were calculated with Mantel-Haenszel (MH) method for dichotomous outcomes. All the estimates were reported with 95% confidence intervals (CIs). Chi-square test was used to assess the heterogeneity among studies, wherein a P value of  $P < 0.01$  was set for significance.  $I^2$  was used to quantify statistical heterogeneity. If there was a heterogeneity between the studies, a random effect model was used, otherwise a fixed effect model was employed. Sensitivity analyses was performed for the studies that were based on the comparison of the meta-analysis results of all of the included studies and the studies that were excluded due to poor quality. Funnel plots were used to screen for potential publication bias.

Age and gender were considered to have a great influence

on the relative risk observed, however, we failed to control these confounding factors as they were not accounted in most of the studies. T-test and Chi-square test was later performed to analyze whether there were age and gender differences between the HCW group and the control group, respectively. For the other confounding factors such as study period, quality of included literature, and the sampling methods, we performed subgroup analysis of the combined results, which demonstrated the reliability of our meta-analysis.

## Results

### Study characteristics

As shown in *Figure 1*, a total of 1,540 studies were identified through initial search of databases, with 8 studies in English and 12 studies in Chinese. Twenty studies were eventually included after being screened. These studies focused on the prevalence of LTBI (*Table 1*) and were characterized by the cross-sectional study designs. Considering that age and gender had influence on the relative risk observed, we reviewed these factors in all the included studies. Three studies provided data with stratified age and 5 studies classified data based on the gender. In the field of region

\*Study quality were assessed using the scale of Agency for Healthcare Research and Quality (AHRQ).

distribution, 10 studies in eastern China, 8 in central China, 2 in western China were referred. Sources of HCWs population of 13 studies came from TB (or infectious disease) specialised hospitals, 6 from general hospitals and 1 from both. The types of control groups of 12 studies were 'in-hospital' controls comprising of administrative or logistics or management personnel of the hospital. The other 6 studies considered 'community-control' where in the local population was used as control, and 1 considered both. 2 articles from the reference materials were also considered. There were 12 studies based on the diagnosis of LTBI with TST, while 8 studies with IGRA.

### Sensitivity

In the 20 studies describing the prevalence of LTBI, there was a significant heterogeneity between the results after the data was combined. There was significant difference between the HCWs and the control groups ( $I^2=78\%$ ,  $P<0.05$ ), and therefore, a random effect model was used for the combined effect analysis. Sensitivity analysis was performed later by excluding the studies one by one. This exclusion, however, did not lead to significant changes in the results, suggesting that the results of the meta-analysis were robust (Table S2).

### Publication bias

Funnel plots are often used to assess publication bias in the included studies. The funnel plot results of studies describing the prevalence of LTBI appear to be asymmetric, suggesting that there may be some publication bias. There was, indeed a considerable heterogeneity between the studies. The possible reasons of this bias could be attributed to the flaws in the research design, unrigorous research methods and a small sample size, as illustrated by the wide and overlapping CIs (40). Figures have been provided to see the asymmetry (Figure S3).

In order to control the confounding factors, we performed the subgroup analysis of the combined results. First, for the subgroup analysis of the study period, it was observed that the combined OR value of the studies published before 2010 was 2.56 (95% CI, 1.88–3.48), as compared to the OR value of 1.30 (95% CI, 1.02–1.66) ( $P<0.05$ ) observed for the studies published post 2010. The heterogeneity therefore, was significantly reduced with an  $I^2$  83% as compared to 55% ( $P<0.05$ ), as seen in Figure S4. Secondly, for the subgroup analysis of the quality of the

literature, it was found that the combined OR value of the studies depicting a poor quality of data was 2.06 (95% CI, 1.49–2.84), while that with the good quality data was 1.54 (95% CI, 1.22–1.95) ( $P<0.05$ ). Accordingly, the heterogeneity was reduced slightly with the  $I^2$  82% as compared to 70% ( $P<0.05$ ), as seen in Figure S5. Finally, for the subgroup analysis of sampling methods, the combined OR value of the studies involving non-probability sampling method was 2.01 (95% CI, 1.37–2.96), while the studies employing probability sampling method had an OR value of 1.64 (95% CI, 1.36–1.98) ( $P<0.05$ ). The heterogeneity was significantly reduced, with the  $I^2$  85% compared with 58% ( $P<0.05$ ), as seen in Figure S6. Taken together, the risk of LTBI infection among the HCWs was not significantly different and the same trends were observed after controlling the confounding factors such as the study period, the quality of included literature and the sampling method.

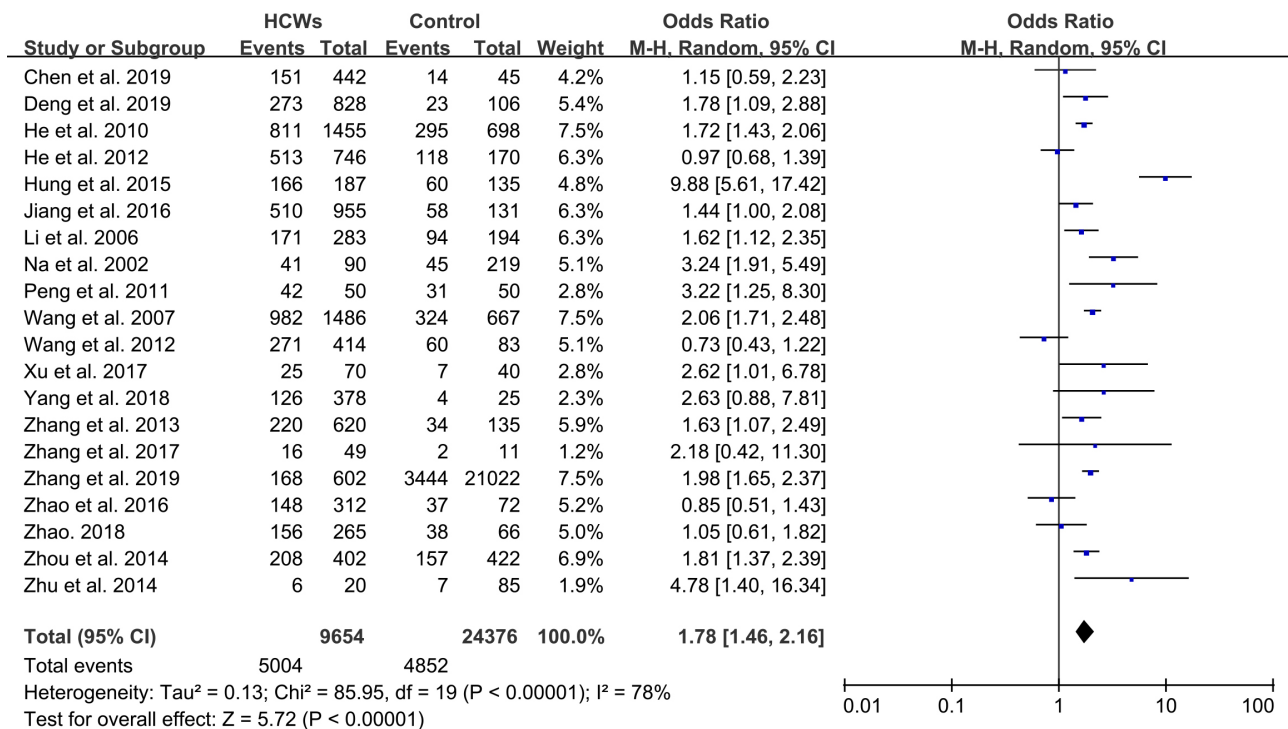

### Prevalence of LTBI

The overall prevalence of LTBI among HCWs varied from 27.9% to 88.8%, and 8.2% to 72.3% in the control groups. HCWs had a higher risk of prevalence of LTBI as compared with the control groups, with an OR of 1.78 (95% CI, 1.46–2.16). In a cross-sectional study conducted in Taiwan, the prevalence of LTBI among HCWs was ranked the highest, reaching 88.8% (Table 1), with an OR value of 9.88 (95% CI, 5.61–17.42; Figure 2).

### Consistent result for the risk of LTBI infection after considering age and gender

As mentioned above in the method section, the age and gender based analysis for most studies were incomplete and therefore, a subgroup analysis could not be performed based on these factors. We however, performed the subgroup analysis by grouping the studies based on the presence of a local control group.

t-test was performed on 3 studies that provided the data with stratified age (Table S3). Chi-square test was performed on 5 studies that provided the data with gender grouping (Table S4). The above test results indicated whether there were age and gender differences between the HCW group and the control group. The analysis revealed that there was no statistically significant difference in the age and gender except, the one observed in the Li study (Li *et al.*, 2006). Further, subgroup analysis showed that for studies lacking

**Figure 2** Forest plot showing pooled odds ratio (OR) for LTBI prevalence among HCWs. LTBI, latent tuberculosis infection; HCW, health care worker.

the local controls, the combined OR value of the risk of LTBI among HCWs was not statistically significant (OR, 4.32, 95% CI, 0.89–21.04). In studies with local controls, and poor age and gender comparability, the heterogeneity was large ( $I^2=68\%$ ,  $P<0.05$ ) and therefore, a random model was used. The combined OR value of the risk of LTBI among HCWs was 1.51 (95% CI, 1.24–1.84). In studies with local controls and good age and sex comparability, there was no heterogeneity among the studies ( $I^2=0$ ,  $P>0.05$ ) and therefore, fixed effect model was used for analysing the data. The combined OR value of the LTBI risk among HCWs as depicted by this model was 1.94 (95% CI, 1.50–2.51). The studies with local controls and poor age and gender comparability, and for studies with local controls and good age and gender comparability, the risk of LTBI infection among HCWs was similar and followed the same trend.

#### Subgroup analysis of risk for prevalence of LTBI among HCWs

In subgroup analyses of geographical location, the highest risk for the prevalence of LTBI among HCWs compared

with the control group was in eastern China (OR, 2.05; 95% CI, 1.35–3.11), followed by the central region (OR, 1.67; 95% CI, 1.33–2.08) and the western region (OR, 1.47; 95% CI, 0.62–3.48) (Figure 3). Secondly, OR for LTBI compared with control groups diagnosed with TST was 1.90 (95% CI, 1.41–2.55), while with IGRA was 1.65 (95% CI, 1.34–2.02). Prevalence diagnosed with TST for LTBI among HCWs ranged from 33.3% to 88.8%, and for control group it was observed to range from 12.0% to 72.3%. When with IGRA, HCWs ranged from 27.9% to 58.9%, while the control groups ranged from 8.2% to 57.6%. Overall, the diagnostic positive rate of LTBI with TST was higher than with IGRA (Figure 4). Thirdly, HCWs had a higher risk for the prevalence of LTBI compared with control groups that were both community-sourced and nosocomial-sourced with a comparative higher OR for the former groups than the later groups [3.12 (95% CI, 1.94–5.01), 1.54 (95% CI, 1.28–1.86)] (Figure 5). Our result indicated that higher risk of LTBI in HCWs was predisposed by the community rather than nosocomial. Furthermore, HCWs in general hospitals had higher risk for the prevalence of LTBI compared with the control

**Figure 3** Forest plot showing pooled odds ratio (OR) for LTBI among HCWs according to geographic regions. LTBI, latent tuberculosis infection; HCW, health care worker.

groups (OR, 2.40; 95% CI, 1.64–3.52). The same trend was also seen in TB or infectious disease specialist hospitals (OR, 1.57; 95% CI, 1.25–1.97) (Figure 6), suggesting that the risk for the prevalence of LTBI among HCWs in general hospitals was higher than TB or infectious disease specialist hospitals.

In subgroup analysis, the control group from community wherein a general hospital and the geographical region located in the eastern China were considered, the HCWs had a higher risk of LTBI prevalence with a combined OR value ranging from 1.90–4.32. On the other hand, for the control group from a TB specialized hospital and the geographical region located in the western region, the HCWs were found to have a relatively low risk of LTBI prevalence with a

combined OR value ranging from 1.47–1.65.

## Discussion

Up to our knowledge, this is the first review presenting the meta-analysis of the China's nationally available data on the prevalence of LTBI among HCWs and control group, wherein the hospital's administrative staff is set as an internal control. After controlling for age and gender, we still see the same trend of the risk for LTBI infection among HCWs in China.

Our results showed an absolute risk of both LTBI and TB to HCWs than that of the general population, which was consistent with studies published earlier (13,18,40,41).

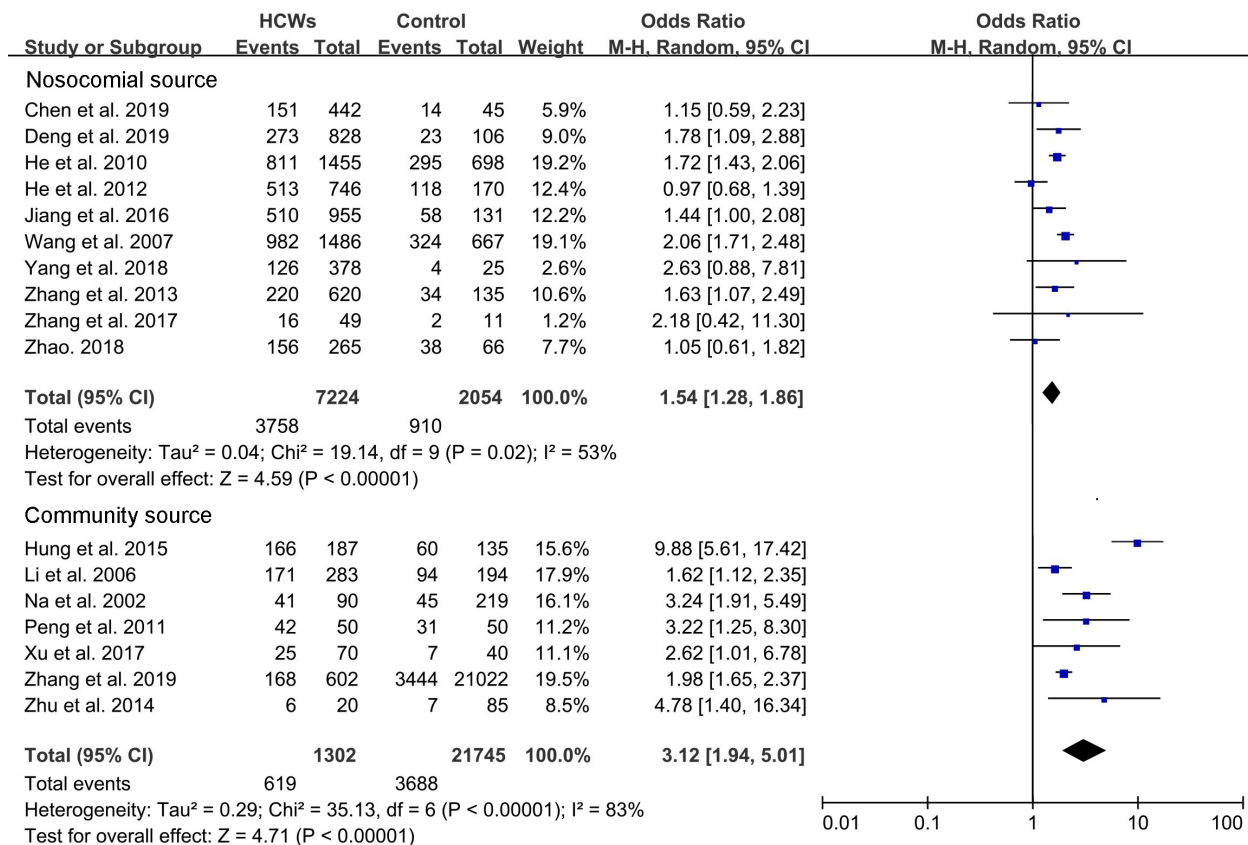

**Figure 4** Forest plot showing pooled odds ratio (OR) for LTBI among HCWs according to the diagnosis methods. LTBI, latent tuberculosis infection; HCW, health care worker.

The prevalence of LTBI among HCWs was 51.5% (ranging from 27.9% to 88.8%), which was congruous with the earlier observations made in the Low- and Middle-Income Countries (LMIC) that depicted a prevalence of 63% (range 33–79%) (13), 54% (range 33–79%) (41) and 37% (range 0.5–62.1%) (18) respectively. Since, LTBI is a reinfection or reactivation of *Mycobacterium tuberculosis* in the host, the former may contribute to a certain degree of immune protection, while the later predisposes to the risk of acquiring an active TB in the future (4). The results of these two interpretations with a diametrically opposite clinical outcome, may also be responsible for the large difference in the prevalence of LTBI among HCWs.

The risk of prevalence of LTBI among HCWs was found to be the highest in the eastern region of China, followed by the central and the western regions. Population density in the eastern region is particularly higher than that of the central and western regions, which leads to a higher

workforce density (42). Furthermore, larger cities attract larger floating population (13) and hence, lead to higher rate of TB (13). The disparity in the economic, educational, and societal setup along with lifestyles variation in different geographic regions (43) in China resulted in HCWs in the eastern regions paying more attention to their health and thereby, resulting in effective reporting of LTBI (44). The results thus, emphasize on the importance of elevating and training HCWs for the management of TB as the most effective measures in preventing TB propagation. The guidelines for LTBI also recommend systematic testing and treatment of LTBI in countries with low TB incidence that may otherwise exhibit high load of LTBI prevalence (45).

The studies included in our meta-analysis involved diagnosing LTBI with TST or IGRA tests that could have led to a wide and overlapping CIs for the prevalence of LTBI. While for most studies a comprehensive description of testing protocols was provided, for a few studies it was

**Figure 5** Forest plot showing pooled odds ratio (OR) for LTBI among HCWs according to the source of control groups. LTBI, latent tuberculosis infection; HCW, health care worker.

found to be obscure and missing important details like which kits of IGRA were used, the exact point for a positive result, whether initial two-step TST was done, how long the TST was observed, and how many units of tuberculin were used. Although, there have been arguments over the techniques best suited for effective diagnosis of LTBI; IGRA has been reported to outperform TST in settings with limited ongoing transmission and/or background prevalence of infection. The TST test, on the other hand, outperformed IGRA when the incidence and prevalence were high such as in case of an epidemic or a situation posing a high risk of infection, or when a study design warranted identification of as many infected individuals, as possible (46). It is important to note that the Bacille de Calmette Guerin (BCG)-vaccination given at birth has been reported to interfere with the results of TST, and leads to an increase in the false positive rates. IGRA however, overcomes this limitation (46). In addition to BCG, *Nontuberculous Mycobacteria* (NTM), occupational as

well as non-occupational exposure to *M. tuberculosis* over the whole lifetime has also been reported to complicate the analysis of the prevalence of LTBI. Given the absence of any case series of nosocomial transmission or outbreaks and the fact that majority of the Chinese population is BCG-vaccinated, IGRA outperformed TST in detecting the prevalence of LTBI among the HCWs. Another important difference reported in literature shows that between IGRA and TST, IGRA is more likely to detect recent infection of TB, whereas TST detects the cumulative exposure to *M. tuberculosis* over time (47,48). Together, our findings highlight that the risk of prevalence of LTBI diagnosed with TST was higher than IGRA and hence, it can be speculated that Chinese HCWs had more cumulative exposure to TB than recent infections. Although, neither TST nor IGRA are gold standards for the diagnosis of LTBI, they are relevant in detecting the host immune response. It is thus, recommended to undertake further combination tests or gene testing techniques to reach to a more accurate and conclusive analysis.

**Figure 6** Forest plot showing pooled odds ratio (OR) for LTBI among HCWs according to the type of hospitals. LTBI, latent tuberculosis infection; HCW, health care worker.

To the best of our knowledge, we are the first to report that the risk of prevalence of LTBI among Chinese HCWs population is largely sourced from the community as against the nosocomial infection. Our results differ from the previous findings that reflected that LTBI among HCWs is primarily derived through nosocomial infections (13). These earlier studies however, lacked comparable or contemporaneous controls and only relied on national data for analysis. Moreover, no studies from China were included in their analysis (13). Uden and his Colleagues did provide a comparable and contemporaneous control data as well as, research data from China, but it did not provide evidence for the source of infection, whether nosocomial or community-derived (18). We suggest that further molecular research studies involving DNA fingerprinting, rather than TST or IGRA, must be undertaken to provide verifying evidence of nosocomial contagion (41).

Among the different type of hospitals that we studied, we observed that HCWs in general hospitals showed a higher

risk of prevalence of LTBI. This trend was consistent with that in the subgroup analysis of community and nosocomial source, as discussed above. This could be partly because the risk of prevalence of LTBI among HCWs in general hospital is primarily community-sourced.

There are still some limitations in our meta-analysis. First, our study did not analyze age stratification and gender comparability. However, we compared the studies with local controls and poor age and gender comparability, and the studies with local controls and good age and gender comparability. Our analysis showed that the risk of LTBI infection among HCWs remains the same and follows the same trend. This might reflect a more complex aspect of the problem. Secondly, it is notable that a systemic review has its own limitation of publication bias, multiple publication bias and the possibility to miss out the studies being researched. In our analysis, we observed a considerable heterogeneity between the studies, reflecting different settings and populations. HCWs have always

been concerned about the risk of developing TB, which might have remained under reported due to heterogenic composition of professionals involved in healthcare services. However, the majority of studies included in our dataset had a clear inclusion criterion for HCWs and control groups that reduced the selection bias. Finally, publications only in English and Chinese were included, which may result in language bias. However, only Chinese HCWs were the main focus of our study where the relevant published data/papers are in English and Chinese language in majority.

In the end, it is true that the precise prevalence of LTBI in the Chinese HCWs population is not accurate and is also difficult to estimate precisely. We attempt to ignite Chinese scholars to take an interest in this real and complex situation about LTBI in China. The observed complexity is a result of pitfalls in the methodologies. For example: a positive TST can be a false positive if not followed by an IGRA due to a BCG vaccination or to a previous TST. The absence of clear distinctions based on age and gender also results in lacking of another important information—the elderly are expected to be more vulnerable to LTBI. Furthermore, the presence of internal controls within a hospital may not be considered as ideal comparison due to the airborne infection risk, even they are not directly dealing with the patients. All the above observations should be considered for developing a better understanding of the spread of infection amongst the working populations exposed to the risk in China.

## Conclusions

We provide a national epidemiological basis for the development of LTBI management in HCWs in China. Our study shows that that risk of LTBI infection among HCWs was relatively high in China, especially in the eastern region. Furthermore, we observe that the primary source of LTBI is cumulative exposure to *Mycobacterium TB* infection, derived from the community. Compared to TB specialized hospitals the associated risk was found to be higher in the HCWs of the general hospitals. Overall, our result emphasizes on a pressing need to strengthen the national policies in China so as to curb the spread of LTBI among HCWs. In order to protect the HCWs, the hospitals need to adopt and implement the following approaches: (I) education services need to be provided for the occupational risks associated with LTBI; (II) personal protective equipments must be provide to prevent contraction of infection; (III) effective

screening and treatment should be supplied. In addition, the methodology and the subsequent limitations presented in current study might serve as instrumental approaches for more comprehensive and accurate study designs involving gender, age, type of hospitals and geography, which may help improve estimating accuracy of the LTBI prevalence in HCWs. Thus, our study provides strong basis for the formulation of strategies to effectively curb the high prevalence of LTBI in HCWs as well as other individuals in China.
