Aims

Hyperkalaemia in heart failure patients limits use of cardioprotective renin–angiotensin–aldosterone system inhibitors (RAASi). Sodium zirconium cyclosilicate (ZS-9) is a selective potassium ion trap, whose mechanism of action may allow for potassium binding in the upper gastrointestinal tract as early as the duodenum following oral administration. ZS-9 previously demonstrated the ability to reduce elevated potassium levels into the normal range, with a median time of normalization of 2.2 h and sustain normal potassium levels for 28 days in HARMONIZE—a Phase 3, double-blind, randomized, placebo-controlled trial. In the present study we evaluated management of serum potassium with daily ZS-9 over 28 days in heart failure patients from HARMONIZE, including those receiving RAASi therapies.

Methods and results

Heart failure patients with evidence of hyperkalaemia (serum potassium ≥ 5.1 mmol/L, $n = 94$) were treated with open-label ZS-9 for 48 h. Patients ($n = 87$; 60 receiving RAASi) who achieved normokalaemia (potassium 3.5–5.0 mmol/L) were randomized to daily ZS-9 (5, 10, or 15 g) or placebo for 28 days. Mean potassium and proportion of patients maintaining normokalaemia during days 8–29 post-randomization were evaluated. Despite RAASi doses being kept constant, patients on 5 g, 10 g, and 15 g ZS-9 maintained a lower potassium level (4.7 mmol/L, 4.5 mmol/L, and 4.4 mmol/L, respectively) than the placebo group (5.2 mmol/L; $P < 0.01$ vs. each ZS-9 group); greater proportions of ZS-9 patients (83%, 89%, and 92%, respectively) maintained normokalaemia than placebo (40%; $P < 0.01$ vs. each ZS-9 group). The safety profile was consistent with previously reported overall study population.

Conclusion

Compared with placebo, all three ZS-9 doses lowered potassium and effectively maintained normokalaemia for 28 days in heart failure patients without adjusting concomitant RAASi, while maintaining a safety profile consistent with the overall study population.

Introduction

Hyperkalaemia is a life-threatening condition associated with serious cardiac arrhythmias, conduction system abnormalities, and increased mortality.^{1,2} The prevalence of hyperkalaemia has been increasing because of higher rates of patients with chronic kidney disease (CKD), heart failure (HF), and diabetes, as well as the broader use of renin–angiotensin–aldosterone system inhibitors (RAASi).^{3–5} Specifically, the growing use of RAASi and mineralocorticoid receptor antagonists (MRAs)—as a result of proven clinical benefit in at-risk populations (particularly those with HF)—has led to higher rates of hyperkalaemia and related hospitalizations and deaths as these agents increase serum potassium levels as a result of their mechanism of action.⁶ Commonly used treatments for hyperkalaemia, such as polymer exchange resins [i.e. sodium polystyrene sulphonate (SPS)] have significant limitations, including not having been evaluated in randomized trials.^{7–9} Furthermore, SPS is poorly tolerated, associated with severe and even fatal gastrointestinal (GI) complications, calling into question its suitability for chronic use.^{10–13} Other management strategies for hyperkalaemia, including restricted dietary intake of potassium and treatments such as insulin, sodium bicarbonate, and inhaled beta-2-adrenergic agonists, have shown limited and temporary efficacy, and are not always feasible.^{14–16}

RAASi, including angiotensin-converting enzyme inhibitors (ACEi), angiotensin receptor blockers (ARB), and MRAs have been shown to decrease morbidity and mortality in patients with HF,^{17–19} but are also known to impair potassium excretion, particularly when given at full dose.^{20–22} Discontinuation or dose reduction of such therapies decreases hyperkalaemia but is associated with substantial long-term risk because of the significant cardiorenal benefit associated with their use. Consequently, although clinical trials have indicated that optimal ACEi, ARB, and MRA dosing may reduce cardiovascular-related hospitalizations and mortality,²¹ utilization studies have demonstrated that RAASi dosing is often not optimized in HF patients,^{23–25} with renal dysfunction and hyperkalaemia frequently cited as barriers to optimal application of RAASi in daily clinical practice.^{26–28}

Several studies have documented that only approximately one-third of HF patients eligible for RAASi therapy are receiving the target dose.^{29,30} Optimal dosing of RAASi may be increased in patients with HF, if hyperkalaemia is addressed and properly managed in these patients. However, current standard-of-care therapies for hyperkalaemia, including agents such as SPS, have uncertain efficacy, poor tolerability, and are associated with severe GI toxicity.^{10,31} There is a clinical need for agents that can reliably and safely reduce serum potassium in patients with HF, and effectively maintain normal potassium in patients who are receiving RAASi.

Sodium zirconium cyclosilicate (ZS-9) is an orally administered, non-absorbed, highly selective K⁺ ion trap, which binds potassium even in the presence of competing ions throughout the intestinal tract. Preclinical studies have suggested that ZS-9 exerts its greatest effects in the duodenum.³² The results of two recently published phase 3 randomized trials in over 1000 patients demonstrated that ZS-9 rapidly normalized serum potassium levels and maintained

potassium in the normal range in a broad cross-section of hyperkalaemic patients.^{33,34} In the phase 3 Hyperkalaemia Randomized Intervention Multidose ZS-9 Maintenance (HARMONIZE) study of 258 patients with hyperkalaemia, treatment with ZS-9 resulted in rapid and significant reductions in potassium from 5.6 mmol/L at baseline to 4.5 mmol/L at 48 h, with a median time to normalization of 2.2 h. After achieving normal potassium levels, patients were randomized to receive placebo (treatment withdrawal) or ZS-9 (5, 10, or 15 g) for 28 days; during this randomized phase, all three doses of ZS-9 resulted in significantly lower potassium levels and greater proportion of patients maintaining normokalaemia vs. placebo, while demonstrating a safety profile similar to placebo, with no ZS-9 treatment-related serious adverse events and no impact on magnesium.³⁴

In this study, we specifically focused on the efficacy of ZS-9 in maintaining normal potassium levels in HF patients who participated in the HARMONIZE study.

Methods

Study population

The details of the HARMONIZE study are reported elsewhere.³⁴ The study recruited adult ambulatory patients with hyperkalaemia (serum potassium ≥ 5.1 mmol/L) from 44 cardiology, nephrology and general research sites in the USA, Australia, and South Africa (March–August 2014). Key exclusion criteria were renal dialysis, active and significant cardiac arrhythmias and treatment with SPS. Patients initially received open-label ZS-9 10 g TID for 48 h; those achieving normokalaemia (serum potassium 3.5–5.0 mmol/L) were randomized (4:4:4:7) to ZS-9 (5, 10 or 15 g) or placebo once daily for 28 days (Figure 1). Concomitant medications could not be adjusted per protocol. Patients completing the randomized phase were eligible for entry in an 11-month open-label extension phase. For this analysis, we specifically focused on patients with a history of HF who participated in the HARMONIZE trial. Patients who developed significant hypokalaemia (serum potassium < 3.0 mmol/L) at any time, severe hyperkalaemia (serum potassium > 6.2 mmol/L) or significant arrhythmias (ventricular tachycardia/fibrillation, new atrial fibrillation/flutter, paroxysmal supraventricular tachycardia, second- or

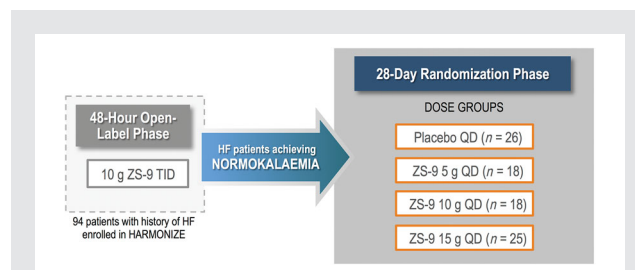

Figure 1 Study design overview. Patients with hyperkalaemia and a history of heart failure (HF) in the Hyperkalaemia Randomized Intervention Multidose ZS-9 Maintenance (HARMONIZE) study received ZS-9 10 g during the 48-h open-label phase. Those who achieved normokalaemia were randomized to placebo (randomized withdrawal) or ZS-9 (5 g, 10 g, or 15 g) for 28 days.

third-degree atrioventricular block or significant bradycardia [heart rate <40 bpm]) during the maintenance phase were withdrawn from the study and referred to their treating physician.

The study was conducted in accordance with the ICH E6 (R1) guidelines of good clinical practice and the declaration of Helsinki. The study was approved by national regulatory authorities in each country and the institutional review board or local ethics committee for each site.

Potassium measurements

All potassium levels were measured (after an 8-h fast) in whole blood with a point-of-care device (i-STAT; Abbott Laboratories, Princeton, NJ). All samples were then sent to a central laboratory for analysis (AU680 chemistry analyzer; Beckman-Coulter, Brea, CA). Patient eligibility for randomization was based on i-STAT potassium values in the morning of study day 3 (following 48 h of treatment with ZS-9 at 10 g, this times daily, TID, to lower potassium). Following randomization, potassium was measured pre-dose on select days throughout the 28-day randomized phase of the study. Statistical analyses were based on central laboratory values. No protocol-directed advice on dietary potassium was provided to patients.

The primary outcome for this analysis was mean serum potassium, determined from days 8 to 29 after randomization. Other outcomes included the proportion of patients that were normokalaemic (mean potassium <5.1 mmol/L) during days 8–29 following randomization and adverse events. Per protocol, secondary objectives of HARMONIZE included evaluation of safety and efficacy of ZS-9 in patients with HF. Patients in HARMONIZE who met eligibility criteria could enrol in an open-label extension phase of once-daily ZS-9 for 11 months (NCT02107092).

Statistical analysis

All statistical analyses were conducted as previously described.³⁴ Briefly, a longitudinal generalized estimating equation (GEE) model was used to simultaneously compare each active dose (highest to lowest) vs. placebo for the mean day 8–29 values. The GEE model is a repeated measure, mixed effect model. Fisher Exact test was used to measure proportion of normokalaemic patients at measured time-intervals and patients with mean day 8–29 potassium <5.1 mmol/L. For the open-label phase efficacy endpoints, change from baseline in potassium at all time-points were assessed using one-sample t-test to test the null hypotheses that the mean changes from baseline were 0. A two-sided *P*-value of <0.05 was considered statistically significant for all endpoints. All analyses were conducted using SAS v9.1 (SAS Institute, Inc., Cary, NC, USA).

Results

Study population

Of 94 patients who had a history of HF at baseline, 87 (93%) achieved normokalaemia after 48 h of ZS-9 treatment and were randomized to either once-daily ZS-9 at the 5 g (*n* = 18), 10 g (*n* = 18), or 15 g (*n* = 25) dose, or placebo (*n* = 26). Of the seven patients who were not randomized, two withdrew consent before completing the open-label phase, and five completed the 48-h open-label phase but withdrew because they did not meet the

serum potassium target (3.5–5.0 mmol/L; *n* = 4), as determined by a local i-STAT device, or did not meet electrocardiogram (ECG) withdrawal criteria (*n* = 1).

Baseline characteristics are listed in Table 1. Across patients, the median age was 69 years, 64% were male, and 86% were white; 71% of patients had a history of diabetes mellitus, 76% had a history of chronic kidney disease, and 81% had estimated glomerular filtration rate (eGFR) of <60 mL/min.1.73 m². At baseline, 69% of patients were treated with RAASi (44% on ACEi, 23% on ARB, and 11% on MRA), which were continued for the duration of the study in all patients receiving these agents. Of these patients, 43% had mild hyperkalaemia (serum potassium 5.0 to <5.5 mmol/L), 45% had moderate hyperkalaemia (serum potassium 5.5 to <6.0 mmol/L), and 13% had severe hyperkalaemia (potassium ≥6.0 mmol/L) at baseline.

Efficacy

Before randomization, the mean baseline serum potassium in 94 patients with HF was 5.6 mmol/L [95% confidence interval (CI) 5.5–5.7], which was normalized to 4.4 mmol/L (95% CI 4.3–4.5) after 48 h of ZS-9 treatment (Figure 2). The median time to normalization was 2.0 h. Within 24 h, 90% of patients had serum potassium <5.1 mmol/L; within 48 h, 99% of patients had serum potassium <5.1 mmol/L.

During the 28-day randomized withdrawal phase, patients in the 5 g, 10 g, and 15 g dose groups maintained lower serum potassium levels at 4.7 mmol/L (95% CI 4.5–4.9), 4.5 mmol/L (95% CI 4.3–4.6), and 4.4 mmol/L (95% CI 4.2–4.5), respectively, compared with patients on placebo who returned to hyperkalaemia [5.2 mmol/L; 95% CI 5.0–5.4; *P* < 0.001, ZS-9 (all doses) vs. placebo; Figures 3 and 4]. Greater proportions of HF patients receiving ZS-9 maintained normokalaemia (mean potassium <5.1 mmol/L, days 8–29) during the randomized phase (83%, 89%, and 92% of patients in the 5 g, 10 g, and 15 g dose groups, respectively) compared with the placebo arm [40%; *P* < 0.01 for ZS-9 (all doses) vs. placebo]. Efficacy findings were consistent among HF patients regardless of continued concomitant RAASi medication.

Safety

Adverse events were reported in 10 HF patients (10.6%) in the 48-h open-label phase; nausea and dizziness were the most common, occurring in two patients (2.1%) each. Adverse events occurring in two or more HF patients after randomization are presented in Table 2. The most commonly reported adverse event during the maintenance phase was oedema, occurring in one, two, and five patients in the 5 g, 10 g, and 15 g dose groups, respectively, and one patient in the placebo arm. Eight of the nine cases were peripheral oedema, four of which did not require treatment despite continued ZS-9 dosing, and no patient discontinued the study because of oedema. Generalized oedema occurred in one patient with severe HF and a history of oedema requiring diuretic treatment. This occurrence of oedema was attributed to discontinuation of diuretics by the patient's family physician before initiation of the study.

Table 1 Baseline characteristics of heart failure patients by treatment arm

	Open-label phase	Randomized phase			
	ZS-9 10 g (n = 94)	Placebo (n = 26)	ZS-9 dose

^aHistory of chronic kidney disease or diabetes mellitus collected at study entry.

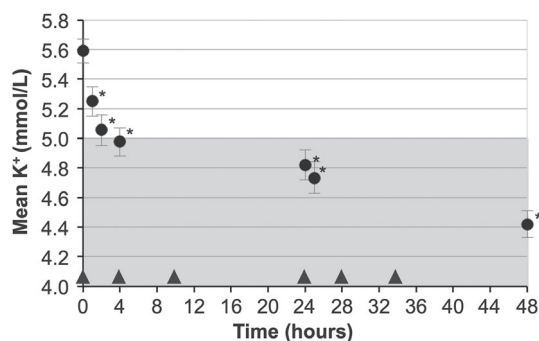

Figure 2 Mean serum potassium over time in patients treated with ZS-9 10g three times daily (circles) for 48h during the open-label phase. The shaded portion represents normal potassium levels. Bars indicate 95% confidence intervals. Triangles indicate administration of ZS-9 dose. * $P < 0.001$ for comparisons against placebo.

Six of the nine oedema patients entered the extension study, continuing once-daily ZS-9, and none have experienced new oedema (with 149 total exposure weeks). No patient receiving 15g doses of ZS-9 in the extension study has experienced oedema (with 278 total exposure weeks). Notably, the oedema rate in HF patients in

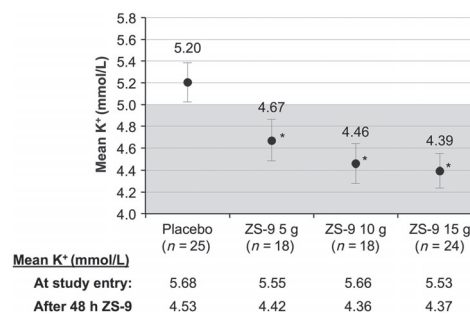

Figure 3 Mean serum potassium, days 8–29 after randomization, placebo vs. ZS-9 5g, 10g, and 15g dose groups. Mean baseline serum potassium values before and after 48h of ZS-9 treatment are shown below the graph for each dose group. The shaded portion represents normal potassium levels. Bars indicate 95% confidence interval. * $P < 0.001$ for comparisons against placebo.

the extension study is numerically lower than the oedema rate in HF patients on placebo during the randomized phase (0.00119 vs. 0.00132 oedema per day of exposure).

Gastrointestinal events were reported in five patients (5.3%) during the open-label phase. After randomization, GI events occurred

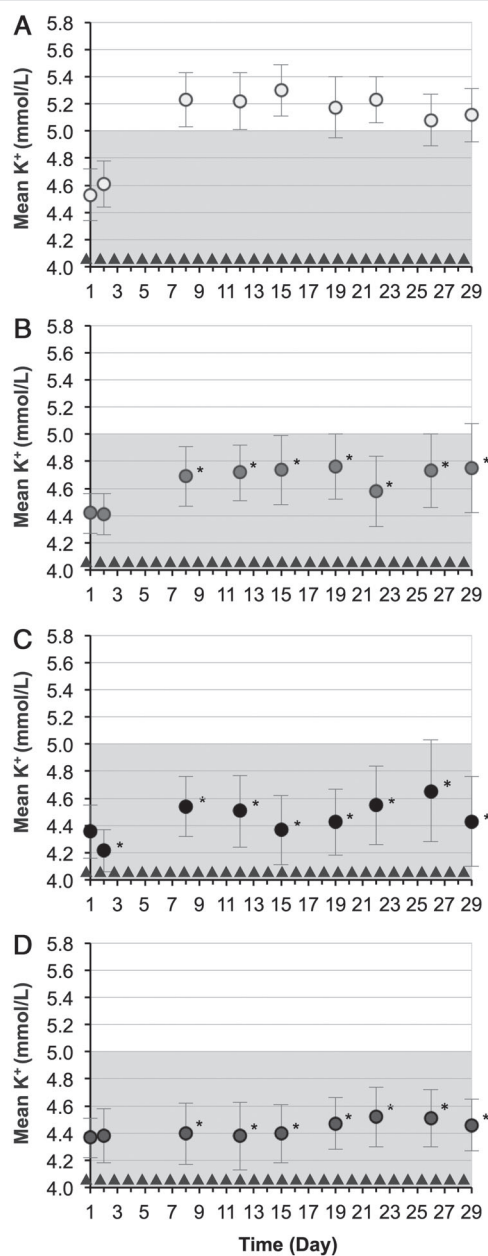

Figure 4 Mean serum potassium over time for the duration of the study (circles): (A) placebo ($n=25$), (B) ZS-9 5 g dose group ($n=18$), (C) ZS-9 10 g dose group ($n=18$), and (D) ZS-9 15 g dose group ($n=24$). Triangles indicate administration of ZS-9 dose or placebo. The shaded portion represents normal potassium levels. Bars indicate 95% confidence intervals. * $P < 0.05$ for comparisons against placebo.

in one patient (5.6%) in the 5 g dose group, none in the 10 g dose group, and three (12%) in the 15 g dose group, compared with five (19.2%) in the placebo group. No clinically significant cases of hypokalaemia (serum potassium < 3.0 mmol/L) or cardiac arrhythmias occurred. Laboratory analyses showed mild hypokalaemia (3.0 to < 3.5 mmol/L) occurring in one patient in the 10 g dose group

and three patients in the 15 g dose group; each case resolved with protocol-directed dose adjustments. None of the cases of hypokalaemia were reported as adverse events. There were no treatment-related serious adverse events in any ZS-9 dose groups.

Discussion

Angiotensin-converting enzyme inhibitor, ARB, and MRA therapy are cornerstones of modern HF therapy, decreasing morbidity and mortality in patients with HF. Unfortunately, these RAASi therapies impair potassium excretion, thereby causing or exacerbating hyperkalaemia. The development of hyperkalaemia in HF patients often results in the reduction RAASi dosage to a level that is suboptimal for the treatment of their cardiovascular disease. Our current options for hyperkalaemia are not ideal given that they are transient, require active management, and are invasive and expensive. For example, treatments such as insulin, sodium bicarbonate, and inhaled beta-2-adrenergic agonists cause a temporary intracellular shift of potassium, dialysis is costly and invasive, and organic polymer resins have not been evaluated in randomized trials and are associated with severe GI complications.

In the present paper we describe the safety and efficacy of once-daily ZS-9 to achieve and maintain normokalaemia in HF patients with hyperkalaemia. Our findings in HF patients with hyperkalaemia demonstrate that, compared with placebo, once-daily ZS-9 resulted in lower potassium levels and greater proportion of patients who maintained normokalaemia for up to 4 weeks. The majority of patients (69%) received RAASi during the study and achieved and maintained normokalaemia without adjustment of their RAASi dose. The data described here in HF patients are consistent with results from two phase 3 randomized controlled trials where ZS-9 rapidly normalized serum potassium within hours and continued to maintain normal potassium for up to 28 days in a high proportion of patients on all ZS-9 doses, all ZS-9 doses reduced serum aldosterone, and efficacy was similar across patients on and not on RAASi. These results suggest that in HF patients, including those on ACEi, ARB, and/or MRA, ZS-9 demonstrated a safety profile similar to the overall HARMONIZE population, was fast-acting with a median time to serum potassium normalization of 2 h, and maintained normokalaemia in patients with HF without the need to reduce or cease life-saving RAASi therapies.

The results of this study should be interpreted in the context of several potential limitations. First, our analysis focused on the subgroup of patients with HF from the HARMONIZE study population, the numbers of patients within each treatment subgroup were small, and interpretability of the results must take into consideration the limitations inherent to treatment in a clinical trial setting. A diagnosis of HF was established based on patient history; no data were collected on New York Heart Association (NYHA) class, echocardiogram, or ejection fraction of enrolled patients. Second, hospitalized patients, those receiving dialysis, and those with life-threatening arrhythmias were excluded from the HARMONIZE trial. Third, although the findings of this study support the ability of ZS-9 to enable continuation of RAASi use in HF patients, additional

Table 2 Summary of all adverse events occurring in two or more patients in any treatment arm

Adverse event, n	Placebo (n = 26)	ZS-9 dose		
		5 g (n = 18)	10 g (n = 18)	15 g (n = 25)
Any event	9	10	7	15
Oedema ^a	1	1	2	5 ^b
Fatigue	0	0	1	2
Anaemia	0	0	0	2
Nasopharyngitis	1	0	0	2
Upper respiratory tract infection	0	2	0	0
Hypertension	1	1	1	2

^aEight of the nine cases were peripheral oedema, four of which did not require treatment despite continued ZS-9 treatment, and no patient discontinued the study because of oedema. Six of nine patients entered the extension study and none have experienced new oedema (149 total exposure weeks).

^bGeneralized oedema occurred in one patient with severe heart failure and a history of oedema requiring diuretic treatment. This occurrence of oedema was attributed to discontinuation of diuretics by the patient's family physician before initiation of the study.

studies will be valuable in confirming whether ZS-9 use can enable up-titration or optimal dosing of RAASi in these patients. Finally, the HARMONIZE trial followed patients for up to 4 weeks, therefore the long-term evaluation of ZS-9 efficacy and safety would be valuable and these studies are currently ongoing.

In conclusion, compared with placebo, all three doses of ZS-9 resulted in lower potassium levels and effectively maintained normokalaemia for 28 days in hyperkalaemic patients with HF, including those on RAASi. These data suggest that ZS-9 may enable continuation of important RAASi use in patients with HF and represents a promising addition to the future of HF therapy.
