(Received January 31, 2017; Revised March 14, 2017; Accepted March 14, 2017)

Bisphenol A (BPA) is a monomer used in a polymerization reaction in the production of polycarbonate plastics. It has been used in many consumer products, including plastics, polyvinyl chloride, food packaging, dental sealants, and thermal receipts. However, there is little information available on the inhalation toxicity of BPA. Therefore, the aim of this study was to determine its inhalation toxicity and effects on the estrous cycle, spatial learning, and memory. Sprague-Dawley rats were exposed to 0, 10, 30, and 90 mg/m³ BPA, 6 hr/day, 5 days/week for 8 weeks via whole-body inhalation. Mortality, clinical signs, body weight, hematology, serum chemistry, estrous cycle parameters, performance in the Morris water maze test, and organ weights, as well as gross and histopathological findings, were compared between the control and BPA exposure groups. Statistically significant changes were observed in serum chemistry and organ weights upon exposure to BPA. However, there was no BPA-related toxic effect on the body weight, food consumption, hematology, serum chemistry, organ weights, estrous cycle, performance in the Morris water maze test, or gross or histopathological lesions in any male or female rats in the BPA exposure groups. In conclusion, the results of this study suggested that the no observable adverse effect level (NOAEL) for BPA in rats is above 90 mg/m³/6 hr/day, 5 days/week upon 8-week exposure. Furthermore, BPA did not affect the estrous cycle, spatial learning, or memory in rats.

Key words: Bisphenol A, NOAEL, Whole-body inhalation toxicity, Estrous cycle, Morris water maze test, Endocrine disruptor chemicals

INTRODUCTION

Bisphenol A [BPA; (CH₃)₂C(C₆H₄OH)₂, CAS No. 80-05-07], white to tan flakes or a powder with a mild odor, is a monomer used in a polymerization reaction in the production of polycarbonate plastics (1). BPA is manufactured through the combination and condensation of acetone with phenol under high temperatures and a low pH, followed by the purification of the product (2). BPA is one of the largest-volume chemicals manufactured worldwide; thus, its global production reached 4.6 million tons in 2012 (3). It has been used in many consumer products, including plastics, polyvi-

nyl chloride, food packaging, dental sealants, and thermal receipts, and humans are usually exposed to BPA through inhalation, diet, and dermal contact (4).

BPA is widely known as an endocrine disruptor chemical (EDC), i.e., a chemical that mimics, alters, and blocks the endogenous hormonal activity. Changes in hormone levels, actions, or receptors through exposure to EDCs disrupt not only the structure and function of the brain but also the regulation of hormones by the brain (1). There is much evidence showing that BPA mimics estrogens and is similar to other estrogenic disruptors. It can also bind to the androgenic receptor and disrupt the action of androgens (5,6).

Numerous studies have reported changes in reproductive hormones caused by the exposure to BPA in experiments (7-9). Effects of BPA exposure on the oocyte, developing reproductive tract, and sexual maturation have been observed in female rats and mice during the perinatal period (10-12). In human studies, BPA exposure has been related to hormone-dependent tumors such as breast and prostate cancer, endocrine disorders such as precocious puberty, and metabolic disorders such as obesity and polycystic ovary syndrome (13). In addition, many studies have reported that

BPA exposure affected the brain development and behaviors during the gestational period. Perinatal or neonatal BPA exposure was shown to influence the brain sexual differentiation (14,15) and neuronal behavior, leading to cognitive deficits as well as learning and memory impairment (16-20). Furthermore, BPA could affect the juvenile social behaviors in mice (21,22).

Although there have been many studies characterizing the BPA effects on estrogenic activity and the brain, its effects have been rarely studied in laboratory animals by using the inhalation route. Therefore, this study was conducted to characterize the potential inhalation toxicity of BPA upon the whole-body exposure of Sprague-Dawley (SD) rats and its effects on the estrous cycle, spatial learning, and memory.

MATERIALS AND METHODS

Animal maintenance. Seven-week-old, specific-pathogen-free SD rats of both sexes were purchased from Bio Genomics Inc. (Gapyeong, Korea) and acclimated for 1 week. The room was maintained at a temperature of $22 \pm 3^\circ\text{C}$, relative humidity of $50 \pm 20\%$, 12 : 12-hr light : dark cycle, and fresh air ventilation (10~15 changes per hr). The rats were housed singly in stainless steel wire mesh cages (width 750 mm \times length 220 mm \times height 180 mm) and had free access to a commercial rodent diet (PMI Nutrition International, Inc., St. Louis, MO, USA) and filtered tap water. The study was conducted at the Occupational Safety and Health Research Institute, and was approved by the Institutional Animal Care and Use Committee (IACUC-0101).

Test chemical and exposure system. BPA (lot no. 033107) was obtained from Samchun Chemical (Pyeongtaek, Korea). A whole body stainless steel exposure chamber (SIS-20RG, Shibata, Niigata, Japan), including a dust generator (DM-800 and DF-3, Shibata), was used to expose rats to BPA at a concentration of 0, 10, 30, or 90 mg/m³ for 6 hr/day, 5 days/week for 8 weeks. Inhalation exposure procedures were conducted from 10:00 to 16:00. The experimental design was based on the routine working schedule of employees and the major exposure route for the test substance.

Conditions in inhalation chambers. The temperature, relative humidity, pressure, and air ventilation in the chambers were recorded using an environmental controller (ICS-20RG, Shibata). A personal sampler (Sensidyne, St. Petersburg, FL, USA) was used for sampling BPA at a flow rate of 2 L/min through the exposure chamber. The particles were collected from the center of the chamber and captured on mixed cellulose ester membrane filters (pore size: 4.5 μm , diameter: 37 mm; Millipore, Billerica, MA, USA). The distribution of particle sizes was determined using an

Anderson sampler (AN-200, Sibata, Tokyo, Japan) at a flow rate of 28.3 L/min for 20 min.

Experimental groups. A total of 80 rats (40 males and 40 females) were randomly assigned to the following four groups (10 animals per sex per group): control (0 mg/m³), low dose (10 mg/m³), middle dose (30 mg/m³), and high dose (90 mg/m³). All rats were euthanized after 8 weeks of exposure. The BPA concentrations were selected using a scaling factor of 3 because a previous study has reported decreased that a decreased body weight or decreased liver and kidney organ weights were observed at BPA concentrations between 50 and 150 mg/m³ (23).

Clinical signs and body weight. All animals were examined once daily for mortality and clinical signs, and weighed individually immediately before the inhalation exposure on day 1 and once per week thereafter.

Hematology. Five male and five female rats in each group were fasted overnight before the necropsy and blood collection. Blood samples were taken from the abdominal aorta using a syringe with a 21-gauge needle under isoflurane anesthesia (Ilsung Pharm, Seoul, Korea) and collected into vacutainers containing EDTA-3K (Becton Dickinson, Franklin Lakes, NJ, USA). The samples were analyzed within 20 min of collection using an automated hematology analyzer (F-820, Sysmex, Kobe, Japan). The following parameters were determined in this study: total erythrocyte counts, hemoglobin concentration, hematocrit, mean cell volume, mean cell hemoglobin, mean cell hemoglobin concentration, platelet count, and whole leukocyte counts.

Serum biochemistry. Blood samples were centrifuged at 3,000 rpm for 10 min within 1 hr after the collection. The sera were stored at -80°C until analysis. The following serum chemistry parameters were evaluated using an automated analyzer (TBA-20FR, Toshiba Medical Systems, Tochigi, Japan): total protein, albumin, blood urea nitrogen, creatinine, total bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, glucose, and total cholesterol.

Necropsy, organ weight, and histopathological evaluations. Gross examinations of the organs in the cranial, thoracic, and abdominal cavities of the rats were conducted. The absolute and relative (organ to body) weights of the brain, thymus, lung, heart, liver, spleen, kidneys, adrenal glands, testes, and ovaries were measured. The following tissues were removed from each animal at necropsy: the liver, kidney, adrenal glands, heart, lungs, cerebrum, cerebellum, pituitary gland, spleen, seminal vesicles, prostate, testes, epididymides, ovaries, uterus, vagina, tongue, trachea, esophagus, thymus, thyroid gland, stomach, urinary bladder, small/large intestine, eyes/hardian glands, skeletal muscles, sciatic

nerve, pancreas, aorta, mesenteric lymph node, femur, larynx, and nasal cavity. The nasal cavity was sectioned at three levels: posterior to the upper incisors; incisive papilla; and first molar teeth. The eyes were fixed in Davidson's solution, and the testes in Bouin's solution. Other organs were preserved in 10% neutral buffered formalin. All organs were embedded in paraffin, sectioned at 3–4 μm , stained with hematoxylin and eosin, and examined microscopically under low- and high-power fields.

Vaginal cytology. Five female rats in each group were evaluated for changes in their estrus cycles for 9 days as previously described (24). Vaginal smears were collected every afternoon, stained with a Giemsa solution, and observed microscopically. The estrous cycle, reflected by the vaginal smear, was characterized as proestrus, estrus, metestrus, or diestrus according to the features of each cell type.

Morris water maze test. Five male and five female rats from the control and 90 mg/m^3 groups were evaluated for their spatial learning ability and memory for 3 days as previously described (25). A circular swimming pool (150 cm in diameter and 50 cm in height) was filled to a depth of 30 cm with water that was maintained at $25 \pm 2^\circ\text{C}$ and dyed with a white colored dye (Tempera; Fine Art Supplies, Auckland, New Zealand). Four equally spaced points were designated as the east, south, west, and north around the edge of the pool. An escape platform was set 1 cm below the water surface. The paths of the mice were recorded using an HVS image-tracking system (HVS Image, Hampton, UK). Each subject performed the task three times daily at intervals of 1 min, and the trials started by placing a rat in the water so that the animal faced the wall surrounding the pool. The rats were allowed to swim to the platform, and the escape latency was recorded.

Statistical analyses. Differences among the groups in various parameters were determined using the SPSS (version 19.0, IBM, Chicago, IL, USA) or SigmaPlot (version 13.0, SYSTAT, San Jose, CA, USA) software. The homogeneity of variance was analyzed by the Levene's test, followed by either one-way analysis of variance for samples with homogenous variance or the Kruskal-Wallis test for samples with heterogeneous variance. Duncan's or Dunnett's multiple test was used to compare the result of each experimental group with that for the control group if the first result was statistically significant.

RESULTS

Characterization of BPA particles in aerosols and particle size. The average concentrations of BPA during the study were $10.51 \pm 1.59 \text{ mg}/\text{m}^3$, $30.52 \pm 4.28 \text{ mg}/\text{m}^3$, and $88.3 \pm 8.64 \text{ mg}/\text{m}^3$ for the low, medium, and high concen-

tration groups, respectively (Table 1). The sizes of BPA particles mostly ranged from 2.10 to 7.0 μm , which accounted for 75.06% of the total distribution (Table 2).

Clinical signs and body weight. No deaths or adverse clinical signs were observed in any rats exposed to any concentration of BPA. The body weights did not significantly change in any male or female rat exposed to any concentration of BPA compared with the control group (data not shown).

Hematology. No statistically significant hematological changes were observed in any of the BPA-exposed groups compared with the control group (data not shown).

Serum biochemistry. Total cholesterol significantly increased ($P < 0.05$) in female rats exposed to 10 and 90 mg/m^3 BPA compared to those in the control group (Table 3, 4). There were no changes in the other serum biochemical parameters.

Organ weight. The relative organ weight of the adrenal gland significantly increased ($P < 0.05$) in the male rat exposed to 90 mg/m^3 BPA compared to those in the control group (Table 5, 6). There was no change in the weight of the other organs.

Gross and histopathological evaluations. No gross lesion was observed in any BPA group. No test substance-

(data not shown).

Morris water maze test. No significant change was observed in the 90 mg/m³ BPA group compared to the control group (data not shown).

DISCUSSION

This study was conducted to evaluate the potential inhalation toxicity of BPA and its effect on the estrogen activity, spatial learning, and memory by repeatedly exposing SD rats for 8 weeks to BPA at concentrations of 0, 10, 30, or 90 mg/m³ in the air. Although we found some statistically significant differences in the serum chemistry and organ weights between animals exposed to BPA and those from the control group, no pathological or physiological adverse effect was observed in any test.

No clinically relevant sign was observed in any of the rats exposed to any concentration of BPA. Previous reports have indicated that perinatal or neonatal BPA exposure caused a reduction of the birth weight, slowed the growth, decreased the survival rate, delayed the puberty in the offspring (26-29), caused gestational diabetes-like symptoms in pregnant animals (30), affected the neurological behavior, and caused the development of prostate and breast cancer in adult animals (31-33). The timing of exposure to BPA during the life cycle may have contributed to the differences between the previous results and our findings.

An increase of total cholesterol was observed in the female rats exposed to 10 and 90 mg/m³ BPA compared to that in the control group. This change was not considered an adverse effect because it was not observed in the males and was not associated with morphological alterations in the liver or thyroid gland (34).

There were statistically significant increases in the relative organ weight of the adrenal glands in the males from the 90 mg/m³ BPA group compared to those from the control group. However, these changes were not regarded as

adverse effects because they were not accompanied by an increase in the absolute organ weight of the adrenal glands and the absolute and relative organ weight of the adrenal glands in the females from the 90 mg/m³ BPA group, nor were they associated with histopathological alterations in the adrenal glands (34). Meanwhile, a decrease in the liver and kidney weight, accompanied by a dose-dependent decrease of the body weight, was observed in rats and mice that were exposed to 150 mg/m³ BPA for 13 weeks; however, no histopathological alterations were revealed (23). The higher concentration or longer exposure period may have contributed to the differences between the previous results and our findings.

No significant change was observed in the estrous cycle in any of the BPA groups compared to the control group. Meanwhile, early prepubertal subcutaneous injection of BPA to females on postnatal day 8 accelerated the onset of puberty, resulting in an early opening of the vagina in BPA treatment groups and decreased reproductive parameters, including the estrous cycle and ovary weights (35). It is thought that BPA has stronger effects on reproductive organs of infants than on those of adults because the development of reproductive organs is more susceptible to estrogenic compounds during the period of sexual differentiation of the brain at the infant age (36).

In the Morris water maze test, no significant change was observed in the 90 mg/m³ BPA group compared to the control group. However, in another study, the average escape pathlength was extended in the ICR male mice orally exposed to BPA (40 µg/kg/day) for 8 weeks, while no significant effect was observed in the females (37). Differences in species or exposure routes may explain the difference between these results and those obtained in our study. On the other hand, perinatal BPA exposure resulted in sex differences in learning and memory because BPA acts as an antagonist for the androgen receptor in the prefrontal cortex during the perinatal period, inhibiting cognitive ability (38-43).

In conclusion, an 8-week repeated whole-body inhalation

exposure of rats to three concentrations of BPA did not result in any toxic effects in any test. Thus, the no observable adverse effect level (NOAEL) of BPA for rats was considered to be above 90 mg/m³, 5 days/week for 8 weeks. Moreover, BPA did not affect the estrous cycle or spatial learning and memory in rats. The present study provides useful information regarding the lack of toxicity of inhaled BPA.
