Background: This study investigated the factors associated with coronary artery stenosis in outpatients. Furthermore, the usefulness of maximum carotid intima–media thickness (maximum-IMT) as a surrogate marker of coronary artery stenosis was evaluated.

Methods: We conducted a single-center retrospective study. A total of 601 outpatients (338 males; 263 females; mean age, 69.8±10.0 years) who underwent coronary computed tomography angiography between April 2006 and March 2012 were analyzed. The associations between coronary artery stenosis (≥75%) as determined by coronary computed tomography angiography and clinical and laboratory parameters were evaluated by multivariate logistic regression. Validation of maximum-IMT as measured by ultrasonography as a surrogate marker of coronary artery stenosis was analyzed by receiver operating characteristic (ROC) curve analysis.

Results: The estimated glomerular filtration rate (eGFR: mL/min/1.73 m²) (odds ratio [OR] 0.985, *p*<0.01), diabetes mellitus (OR 1.98, *p*<0.05), and maximum-IMT (mm) (OR 1.76, *p*<0.01) were significantly associated with coronary artery stenosis (≥75%). In analysis of each group categorized by identified factors, such as renal impairment (eGFR <60 mL/min/1.73 m²) and diabetes mellitus, the ROC curve of maximum-IMT was significant in the group of patients with diabetes mellitus without renal impairment (*p*<0.01) (cutoff value of maximum-IMT, 2.0 mm; sensitivity, 0.74; and specificity, 0.54) but not in other groups.

Conclusion: Renal impairment, diabetes mellitus, and increased maximum-IMT may be significant risk factors of coronary artery stenosis. Maximum-IMT as measured by ultrasonography may be a useful surrogate marker for coronary artery stenosis in patients with diabetes mellitus without renal impairment but not in other patients.

Keywords: coronary artery stenosis, diabetes mellitus, maximum intima–media thickness, renal impairment

Introduction

Coronary artery disease due to coronary artery stenosis is a major cause of death worldwide, including Japan.¹ The severity of coronary artery stenosis correlates with major cardiac events, such as death by cardiovascular disease, myocardial infarction, and unstable angina.² Therefore, prevention, detection at an early stage, and treatment of coronary artery stenosis are important to protect against development and progression of cardiovascular disease.

Cardiac catheterization is considered as the gold standard for screening of coronary artery stenosis because of its high sensitivity and specificity.³ Additionally, cardiac catheterization subsequently allows performance of coronary intervention if indicated. However, cardiac catheterization is invasive and may have risks of adverse events,

including life-threatening thrombosis resulting in cerebral infarction, myocardial infarction and mesenteric artery occlusion, bleeding, and cardiac tamponade by catheter manipulation.⁴ Therefore, non-invasive examinations for coronary artery stenosis are required.

Coronary computed tomography angiography has recently emerged as a non-invasive imaging modality for assessing coronary artery stenosis. A recent meta-analysis reported that coronary computed tomography angiography has comparable sensitivity and specificity to coronary catheterization.⁵ However, the indication for coronary computed tomography angiography is limited to patients who are highly suspected as having coronary artery stenosis by symptoms, such as chest pain and tightness, electrocardiographic abnormalities, high risk factors of coronary artery disease because of exposure to contrast agents, and X-ray radiation, which may not be beneficial for patients.⁶

Recently, several studies reported that carotid intima-media thickness (IMT) as measured by ultrasonography was correlated with systemic atherosclerosis^{7,8} and coronary artery disease.^{9,10} Several previous studies have also reported that maximum-IMT is a predictor of coronary artery stenosis in patients with diabetes mellitus.¹¹⁻¹³ Evaluation of maximum-IMT as measured by ultrasonography is simple, non-invasive, and repeatable. However, a few studies have examined the utility of maximum-IMT with ultrasonography in various populations, including patients with renal impairment.

Therefore, in this study, we analyzed the association of factors, such as clinical and laboratory parameters, including maximum-IMT as measured by ultrasonography, with coronary artery stenosis in outpatients. Furthermore, we evaluated the usefulness of maximum-IMT as a surrogate marker of coronary artery stenosis in each group categorized by identified risk factors for coronary artery stenosis in outpatients.

Methods

Patients

We retrospectively analyzed clinical and laboratory data of patients who had regularly visited Chiba Prefectural Togane Hospital and underwent coronary computed tomography angiography between April 2006 and March 2012. Coronary computed tomography angiography was performed to examine coronary arteries for the following reasons: chest symptoms, ischemic change on an electrocardiogram, positive exercise stress test, left ventricular wall motion abnormalities on echocardiography, and carotid artery plaques. In all of these patients, carotid artery ultrasonography was routinely performed for screening the severity of systemic atherosclerosis. Exclusion

criteria were patients who had known cardiovascular disease and those receiving renal replacement therapy.

Study protocol

This study was a single-center, retrospective, cross-sectional study. This study was performed in accordance with the ethical principles contained in the Declaration of Helsinki and was approved by the ethics committee of Chiba Cerebral and Cardiovascular Center. Patients' consent to review their medical records was not required by the Ethics Committee of Chiba Cerebral and Cardiovascular Center because this study examined a retrospective cohort by analyzing the past medical history. The patients' data were treated carefully to keep confidentiality. Information on this cohort study, including the patients' right to opt out, was uploaded to the website of Chiba Cerebral and Cardiovascular Center. Laboratory data obtained within 1 month before coronary computed tomography angiography and carotid ultrasound data obtained within 3 months before and after coronary computed tomography angiography were used for analysis. Significant factors that were associated with coronary artery stenosis were analyzed using multivariate logistic regression analysis. Diagnostic accuracy of maximum-IMT for detecting coronary artery stenosis was analyzed using receiver operating characteristic (ROC) curve analysis.

Laboratory methods

Blood and urinary parameters were determined by the Department of Clinical Laboratory, Chiba Prefectural Togane Hospital. Serum glycated hemoglobin (HbA1c) levels are shown as National Glycohemoglobin Standardization Program values. The estimated glomerular filtration rate (eGFR) was calculated using a modified version of the Modification of Diet in Renal Disease formula of the Japanese Society of Nephrology as follows: $eGFR (mL/min/1.73 m^2) = 194 \times age^{-0.287} \times serum \text{ creatinine}^{-1.094}$ (multiplied by 0.739 for females).¹⁴ Hypertension was defined as systolic blood pressure ≥ 140 mmHg and/or diastolic blood pressure ≥ 90 mmHg or current use of antihypertensive agents. Diabetes mellitus was defined as HbA1c levels $\geq 6.5\%$ or use of oral hypoglycemic agents and/or insulin therapy.

Assessment of coronary artery stenosis by coronary computed tomography angiography

The degree of coronary artery stenosis was assessed by coronary computed tomography angiography using a 256-slice multidetector computed tomography scanner (Brilliance iCT; Phillips Healthcare, Cleveland, OH, USA; slice

Figure 1 Visual quantitative grading of coronary artery stenosis using coronary computed tomography angiography. The severity of coronary artery stenosis (arrows) was visually categorized as no stenosis, 1%–24% stenosis, 25%–49% stenosis, 50%–74% stenosis, and $\geq 75\%$ stenosis. Patients with at least one coronary artery stenotic lesion $\geq 75\%$ were considered to have significant coronary artery stenosis.

collimation, $2 \times 128 \times 0.625$ mm³; gantry rotation time, 270 ms) at Chiba-Nishi General Hospital (an affiliated hospital of Chiba Prefectural Togane Hospital). Each coronary computed tomography angiography image was analyzed by two or more experienced cardiologists. In the case where cardiologists had different judgments, interpretation of coronary computed tomography angiography was carefully determined by a conference of cardiologists. The severity of coronary artery stenosis was visually categorized as no stenosis, 1%–24% stenosis, 25%–49% stenosis, 50%–74% stenosis, and $\geq 75\%$ stenosis (Figure 1).¹⁵ Patients with at least one coronary artery stenotic lesion $\geq 75\%$ were considered to have significant coronary artery stenosis.¹⁶

Evaluation of maximum-IMT using ultrasonography

Maximum-IMT was measured using B-mode ultrasound imaging with a 12-MHz linear transducer (Aplio TA700; Toshiba, Tokyo, Japan) at Chiba Prefectural Togane Hospital. Carotid IMT was measured as the distance between two parallel echogenic lines representing the lumen–intima interface and media–adventitia interface on the posterior wall of the artery (Figure 2A).¹⁷ The maximum-IMT was defined as the greatest carotid IMT in observable areas on both sides of the common carotid artery, carotid bulb, and internal carotid artery (Figure 2B). All scans were performed by experienced laboratory technicians. In analysis of the relationship between maximum-IMT and the prevalence of coronary artery stenosis, maximum-IMT was categorized into the following five grades: < 1.1 mm, 1.1–2.0 mm, 2.1–3.0 mm, 3.1–4.0 mm, and ≥ 4.1 mm. This categorization was based on the finding that maximum-IMT was reported to be less than 1.1 mm in healthy Japanese subjects.¹⁸

Statistical analysis

Statistical analysis was performed using JMP 11 (SAS Institute Inc., Cary, NC, USA). Data are expressed as

mean \pm standard deviation for continuous variables and as counts and percentages for categorical variables. Comparisons of component ratios were performed using Fisher's exact test. Comparisons of clinical parameters between the two groups were performed using the Mann–Whitney *U*-test. Logistic regression analysis was used to detect significant predictors of coronary artery stenosis. Parameters that were significantly associated with coronary artery stenosis in univariate logistic regression analysis were included in multivariate logistic regression analysis. The relationship between the category of maximum-IMT and the prevalence of coronary artery stenosis was evaluated by Fisher's exact test. The ability of maximum-IMT to predict coronary artery stenosis was examined by ROC curve analysis. The area under the ROC curve and sensitivity and specificity were calculated for

Figure 2 Longitudinal B-mode ultrasound image of the common carotid artery. **Notes:** IMT was measured as the distance between the lumen–intima (black arrow) and media–adventitia (gray arrow) (A). Maximum-IMT was measured as the thickest IMT value recorded in either the right or left side of the common carotid artery, carotid bulb, and internal carotid artery (double arrow) (B). **Abbreviation:** IMT, intima–media thickness.

detecting coronary artery stenosis. For all tests, p -values less than 0.05 were considered statistically significant.

Results

Patients' characteristics

Patients' characteristics and medications are shown in Table 1. A flow diagram of analyzed patients is shown in Figure 3. A total of 601 patients (338 males, 263 females, mean age: 69.8 ± 10.0 years) underwent coronary computed tomography angiography during the observation period. The reasons for undergoing coronary computed tomography angiography were chest symptoms in 80 (13.3%) patients, electrocardiographic abnormalities in 49 (8.2%) patients, cardiac wall motion abnormalities on an echocardiogram in 169 (28.1%) patients, and carotid artery plaques in 303 (50.4%) patients. Coronary computed tomography angiography showed that 167 (27.8%) patients had coronary artery stenosis of $\geq 75\%$. Among these 167 patients, 158 (94.6%) underwent coronary angiography. Finally, 136 (81.4%) patients underwent percutaneous coronary intervention and seven (4.2%) received coronary artery bypass graft surgery (Figure 3).

Factors associated with coronary artery stenosis

Multivariate logistic regression analysis showed that an eGFR (odds ratio [OR] 0.985, 95% confidence interval [CI] 0.975–0.996; $p < 0.01$), diabetes mellitus (OR 1.98, 95% CI 1.14–3.53; $p < 0.05$), and maximum-IMT (OR 1.76, 95% CI

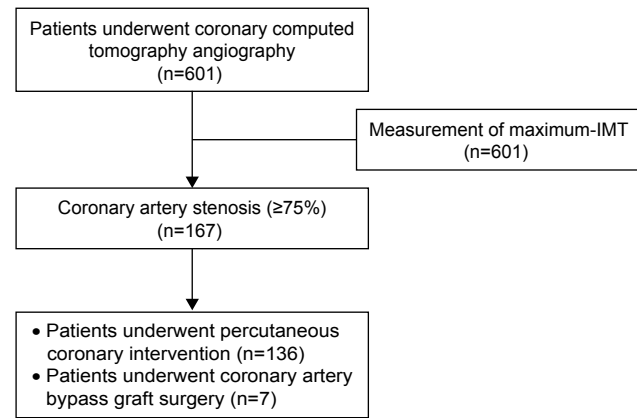

Figure 3 Flow diagram of the analyzed patients. **Abbreviation:** IMT, intima–media thickness.

1.30–2.40; $p < 0.05$) were significant factors associated with coronary artery stenosis ($\geq 75\%$) in all patients (Table 2). The OR of coronary artery stenosis ($\geq 75\%$) was shown to be increased by 1.76-fold for every 1 mm increase in maximum-IMT (Table 2).

Relationship between maximum-IMT and the prevalence of coronary artery stenosis in each group categorized by renal impairment and diabetes mellitus

The degree of maximum-IMT in all of the patients is shown in Table 3. eGFR, diabetes mellitus, and maximum-IMT were significant factors associated with coronary artery stenosis ($\geq 75\%$). Therefore, validation of maximum-IMT as a surrogate marker of coronary artery stenosis was conducted in each group categorized by the presence or absence of renal impairment (cutoff value: eGFR, 60 mL/min/1.73 m²) and diabetes mellitus. Patients' characteristics categorized by the presence or absence of diabetes mellitus and renal impairment are shown in Table 4. The degree of maximum-IMT was significantly associated with coronary artery stenosis in the group of patients with diabetes mellitus (+)/renal impairment (–) ($p < 0.001$), but no association was observed in other groups (Figure 4). Notably, the prevalence of coronary artery stenosis increased to approximately 50%, even in the lower grade of maximum-IMT thickness in patients with diabetes mellitus and renal impairment (Figure 4).

Diagnostic accuracy of maximum-IMT thickness for detecting coronary artery stenosis

The ROC curve of maximum-IMT thickness for detecting coronary artery stenosis was significant in the group of

patients with diabetes mellitus (+)/renal impairment (–) ($p < 0.001$, Figure 5B). In this group, the area under the curve (AUC) for maximum-IMT thickness for predicting coronary artery stenosis was 0.679 (95% CI 0.607–0.750) and the cutoff value with the greatest sensitivity and specificity for maximum-IMT thickness was 2.0 mm (sensitivity, 0.74; specificity, 0.54) (Figure 5B). ROC curves of maximum-IMT thickness for detecting coronary artery stenosis were not significant in other groups of patients, such as those with diabetes mellitus (–)/renal impairment (–), diabetes mellitus (–)/renal impairment (+), and diabetes mellitus (+)/renal impairment (+) (Figure 5).

Discussion

In this study, we investigated the factors that are associated with coronary artery stenosis and validation of maximum-IMT as measured by ultrasonography as a surrogate marker of coronary artery stenosis. We found that renal impairment (decreased eGFR), diabetes mellitus, and increased

maximum-IMT were significantly associated with coronary artery stenosis ($\geq 75\%$) as assessed by coronary computed tomography angiography. We also found that the degree of maximum-IMT was associated with the prevalence of coronary artery stenosis ($\geq 75\%$) in patients with diabetes mellitus without renal impairment but not in other groups of patients. These results suggested that maximum-IMT as measured by ultrasonography could be a surrogate marker for coronary artery stenosis in $\geq 75\%$ in patients with diabetes mellitus without renal impairment.

Several studies have reported that renal impairment and diabetes mellitus are strong risk factors for cardiovascular disease. Diabetes mellitus increases the risk of cardiovascular disease by 3-fold compared with the general population.¹⁹ The degree of renal impairment is associated with an increase in the prevalence of cardiovascular disease.^{20,21} Additionally, diabetes mellitus and renal impairment synergistically increase the risk for developing cardiovascular disease.²² In our study, diabetes mellitus and renal impairment (decreased eGFR) were significant risk factors for coronary artery stenosis ($\geq 75\%$). These results are consistent with previous results^{19–22} and suggest that coronary artery stenosis of these patients should be carefully monitored. In this study, 85.6% (143/156) of patients who had coronary artery stenosis ($\geq 75\%$) that was detected by coronary computed

tomography angiography required catheter intervention. This finding indicates that computed tomography angiography has high sensitivity and specificity for screening coronary artery stenosis as previously reported.⁵

Maximum-IMT is an established surrogate maker of atherosclerosis.^{7,8} Several studies have also reported that increased maximum-IMT is significantly associated with the prevalence coronary artery stenosis in patients with diabetes mellitus.^{11–13} In these studies, the AUCs of maximum-IMT as measured by ultrasonography for the presence of coronary artery stenosis were reported to be 0.71–0.73.^{11–13} In the present study, the AUC of maximum-IMT in the group of patients with diabetes mellitus without renal impairment was 0.68, which is comparable with the results of previous studies.^{11–13} Taken together, these findings suggest that maximum-IMT as measured by ultrasonography is a useful surrogate marker of coronary artery stenosis in patients with diabetes mellitus without renal impairment. However, the degree of maximum-IMT was not associated with the

prevalence of coronary artery stenosis ($\geq 75\%$) in patients with diabetes mellitus (-)/renal impairment (-), diabetes mellitus (-)/renal impairment (+), and diabetes mellitus (+)/renal impairment (+). Regardless of a lower category of maximum-IMT, a high prevalence of coronary artery stenosis was observed in patients with diabetes mellitus (+)/renal impairment (+). Physicians should note this discrepancy between coronary artery stenosis and maximum-IMT when they care for patients with diabetes mellitus and renal impairment. Monckeberg's sclerosis, which is characterized by vascular medial hyperplasia, sclerosis, and calcification, is frequently observed.²³ A previous study showed that a reduced eGFR was associated with increased carotid arterial stiffness without progression of intimal disease, such as increased IMT or plaque formation.²⁴ Additionally, the eGFR is not associated with an increased IMT after adjusting for traditional cardiovascular disease risk factors.^{25,26} Taken together, these findings suggest that maximum-IMT is not a useful surrogate marker of coronary artery stenosis

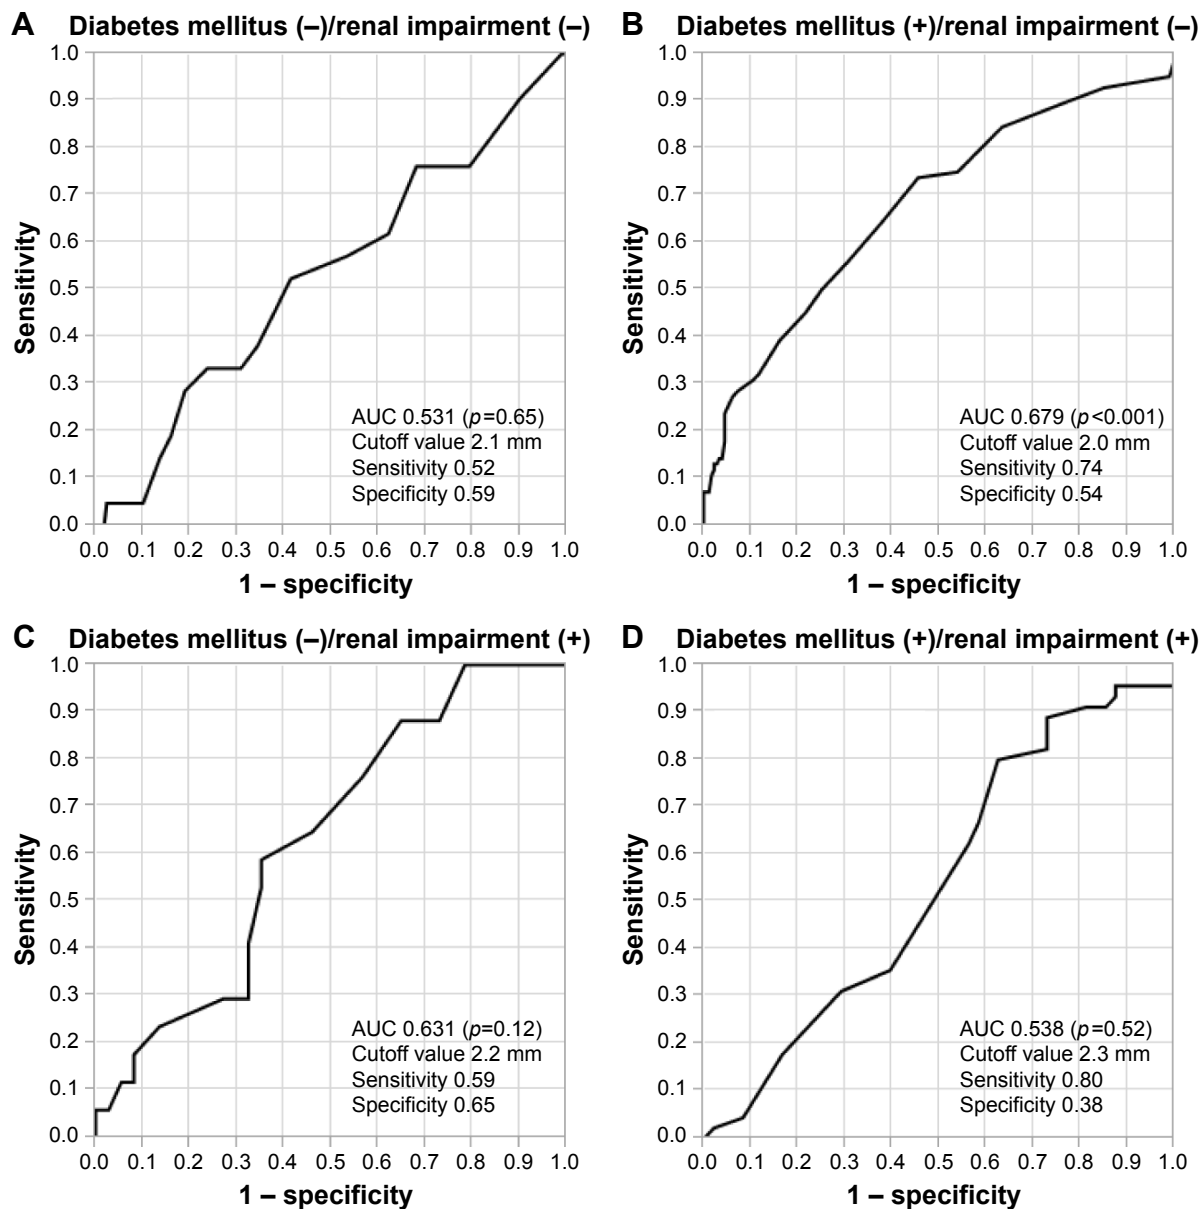

Figure 5 ROC analysis for predicting coronary artery stenosis of $\geq 75\%$ for each group categorized by the presence or absence of diabetes mellitus and renal impairment. **Notes:** (A) The group of patients with diabetes mellitus (-)/renal impairment (-). in patients with renal impairment. Diabetes mellitus and renal impairment synergistically increase the risk of coronary artery stenosis by different mechanisms. Further studies to investigate the mechanism of development coronal artery stenosis and maximum-IMT in diabetes mellitus with renal impairment are required.

This study has several advantages compared with previous studies.^{11–13} First, our sample size was larger than that of previous studies.^{11–13} Second, this study analyzed a diverse patient population, including patients with/without diabetes mellitus and those with/without renal impairment. However, previous studies that investigated associations between

maximum-IMT and coronary artery stenosis only included patients with diabetes mellitus without renal impairment.^{11–13} Therefore, the results of this study may be more helpful in the clinical setting.

There are several limitations in this study. First, this was a single-center, retrospective, observational study, which may have been subjected to patient selection bias. Second, all of the participants were Japanese patients from a single center, which might limit the possibility of generalizing our findings. Third, many of the patients' baseline characteristics, including age and sex, were significantly different among the four groups. Fourth, manual measurement of IMT might have

caused variation and affected the results of this study. Therefore, the possibility that these differences might affect study results cannot be excluded. Further prospective, multicenter, multiethnic studies are required to generalize our findings.

Conclusion

Renal impairment, diabetes mellitus, and increased maximum-IMT as measured by ultrasonography may be significant risk factors of coronary artery stenosis in outpatients. Maximum-IMT may also be a useful surrogate marker to predict the presence of coronary artery stenosis in patients with diabetes mellitus without renal impairment but not in other patients.

Therapeutics and Clinical Risk Management

Dovepress

Publish your work in this journal

Therapeutics and Clinical Risk Management is an international, peer-reviewed journal of clinical therapeutics and risk management, focusing on concise rapid reporting of clinical studies in all therapeutic areas, outcomes, safety, and programs for the effective, safe, and sustained use of medicines. This journal is indexed on PubMed Central, CAS,

EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
