Background: Both *in vitro* and in animal studies have shown immunosuppressive effects of opioids which might provoke tumour growth and metastasis, while no definite results were shown in previous clinical studies. To find out the effects between general anaesthesia combined with sufentanil target-controlled infusion (SGA) and general anaesthesia combined with epidural anaesthesia (EGA) on immunological alterations, stress responses and prognosis in patients undergoing open hepatectomy, a prospective, non-inferiority, randomized-controlled study was performed.

Methods: Patients with liver neoplasms undergoing open hepatectomy were randomly assigned to either SGA (n=81) or EGA (n=81) group. The primary outcome was the ratio of interferon (IFN)- γ /interleukin (IL)-4 at 24 h after surgery (T₃). The secondary outcomes included immune-related cytokines, circulating immune cells, stress-related cytokines, cortisol and blood glucose, visual analogue scale scores. Plasma was sampled at five-time points [baseline/before surgery (T₀), 5 min after portal block release (T₁), 1 h after surgery (T₂), T₃, and on a postoperative day (POD)5 (T₄)]. Cancer-related outcomes, including recurrence, metastasis and survival, were followed up at 3 months and 1 year after surgery.

Results: The IFN- γ /IL-4 ratios were comparable between both groups at T₃ {median [interquartile range (IQR)]: 20.78 (12.73–29.18) vs. 19.52 (13.98–29.29), P=0.607}. At T₃, the proportions of circulating T cells were decreased, while those of B and natural killer cells were increased. The plasma level of tumour necrosis factor (TNF)- α at T₂ was significantly higher in the SGA group [median (IQR): 7.45 (6.20–9.80) vs. 5.95 (4.95–7.45) pg/mL, P<0.001]. Patient-controlled intravenous analgesia was less effective than epidural analgesia on POD0 and POD2. For hepatocellular carcinoma (HCC)-related outcomes, no significant differences were found in either short- or long-term follow-ups.

Conclusions: Although the levels of TNF- α were higher in the SGA group, the tumour-related immunological alterations and follow-ups showed no difference between groups. SGA appears not to be inferior to EGA regarding tumour-related immunity and prognosis. Intravenous opioid use appears not to be inferior to epidural anaesthesia, and can be used safely in HCC patients without worsening patients' prognosis.

Trial Registration: Chinese Clinical Trial Registry (No. ChiCTR2000035299).

Introduction

Globally, cancer is the second major contributor to morbidity and mortality (1,2), and its burden is rapidly increasing. Hepatocellular carcinoma (HCC) is the most frequent primary type of liver cancer and the third leading cause of cancer-related death worldwide (3). Surgical resection is potentially curative with proven survival benefits (2,3), but the 5-year recurrence rate is surprisingly high (~60%) in patients who undergo hepatic resection (4).

Among various perioperative factors linked to cancer recurrence, anaesthesia-related factors, including anaesthetic agents, analgesia techniques and analgesia, remain elusive (5-9). Epidural anaesthesia is used to enhance recovery after surgery because it provides high-quality analgesia (10), thus attenuating the surgery-mediated stress response and preserving the patient's innate immune system (8). A concern regarding thoracic epidural anaesthesia in hepatectomy is possible postoperative prolongation of

the prothrombin time, which may delay epidural catheter removal and increase the administration of corrective blood products (11). In addition, a relative contraindication of epidural anaesthesia is thromboprophylaxis, which is common in patients with atherosclerotic cardiovascular disease, the leading cause of morbidity and mortality globally (12,13). Thromboprophylaxis is also widely used in the perioperative period for deep vein thrombosis prevention, which raises the same concern as that for hepatectomy based on the potential for epidural hematomas.

Unlike epidural anaesthesia, intravenous opioids, as an essential element of general anaesthesia and the standard potent pain-relieving agents for pain in the perioperative period (2,14,15), could be safely used in patients with coagulation disorders. However, in cancer patients, opioids often exert immunosuppressive effects, including modulating cellular and humoral responses, inhibiting natural killer (NK) cell cytotoxicity (16), directly acting on tumour cells, stimulating angiogenesis and interacting with the μ -receptor (17,18), in the regulation of tumour growth and metastasis. Many preclinical studies and retrospective studies suggest that perioperative opioid use may be linked to cancer-promoting effects and lead to inferior oncologic outcomes (19). However, the majority of research focusing on the immune system has involved *in vitro* or animal studies and clinical retrospective studies, which have low translational value, with most evidence deriving from laboratory and retrospective clinical studies (19). Well-designed randomized controlled trials (RCTs) are needed to clarify the relationship between cancer recurrence and anaesthesia-related factors.

In the development of HCC, immunoregulation plays a central role and the T helper (Th) cell subgroups are important parts in orchestrating host immune patterns in perioperative states (20). Under HCC scenarios, Th1 cell subsets mediate anti-tumour effects and result in tumour regression by producing interferon (IFN)- γ . In the meantime, Th2 and regulatory T (Treg) may in contrast inhibit the anti-tumour efficacy (21). Various anaesthesia managements may result in different polarizations of Th subsets, which determine the directions of anti-tumour

Highlight box

Key findings

- Intravenous opioid use appears not to be inferior to epidural anaesthesia and can be used safely in hepatocellular carcinoma (HCC) patients without worsening patients' prognosis.

What is known and what is new?

- Many preclinical studies and retrospective studies suggest that perioperative opioid use may be linked to cancer-promoting effects and lead to inferior oncologic outcomes, while clinical results have been contradictory and elusive for perioperative opioid use.
- We designed a randomized controlled trial (RCT) in HCC patients. Our study was designed to find out whether sufentanil-dominant anaesthesia/analgesia was comparable to epidural anaesthesia/analgesia in affecting immunological alterations, perioperative stress response and also prognosis.

What is the implication, and what should change now?

- Our study results provide evidence for supporting perioperative opioid use in cancer patients without worsening short- and long-term prognosis. More large and well-designed RCTs are needed to ascertain the perioperative opioid use in other types of tumours and surgeries.

responses.

In this study, we compared the effects of sufentanil-dominant anaesthesia/analgesia and epidural anaesthesia/analgesia in HCC patients undergoing open liver resection, including immunological alterations, perioperative stress response and also prognosis by assessing cytokines, immune cells (B cells, T cells, Th cell subsets, NK cells), hormonal changes, short and long-term follow-up (survival, metastasis and recurrence). This entire study was conducted to determine whether the effects of general anaesthesia combined with sufentanil target-controlled infusion (SGA) and patient-controlled intravenous analgesia (PCIA) on the immune system and tumour prognosis are comparable to those of general anaesthesia combined with epidural anaesthesia (EGA) and patient-controlled epidural analgesia (PCEA). We present this article in accordance with the CONSORT reporting checklist (available at <https://jgo.amegroups.com/article/view/10.21037/jgo-23-711/rc>).

Methods

Study design and patients

This study was a randomized, non-inferiority study conducted at a single site (Zhongshan Hospital Affiliated with Fudan University, Shanghai, China). The study was conducted in accordance with the Declaration of Helsinki (as revised in 2013). The study procedures were approved by the Ethics Committee of Zhongshan Hospital affiliated with Fudan University (No. B2020-080R2), and informed consent was taken from all the patients. Patients aged 18–68 years with American Society of Anaesthesiologists (ASA) classification I–II who were diagnosed with liver neoplasms by magnetic resonance imaging (MRI) or ultrasound examination and scheduled to undergo elective open hepatectomy at Zhongshan Hospital were enrolled. The exclusion criteria were: (I) emergency operation; (II) contradictions of epidural (including abnormal coagulation function, platelet count under $100 \times 10^9/L$, and skeletal deformity); (III) allergies to drugs used in the study; (IV) pregnant or lactating; (V) severe heart, lung, liver, kidney, or endocrine disease; and (VI) use of immunosuppressive drugs or corticosteroids.

A total of 170 patients were ultimately enrolled in this study and all participants enrolled were randomly assigned (1:1) into one of two groups: the EGA group and the SGA group. The randomization sequence was generated by a study researcher who was blinded to the

enrolment, using the RAND function in Microsoft Excel (Microsoft Corporation, Redmond, WA, USA) before patient recruitment. The allocation sequence was concealed from the researcher enrolling and assessing participants in sequentially numbered, opaque, sealed envelopes. The corresponding envelopes were opened only on the morning of the surgery.

Anaesthesia technique and grouping method

All patients received a preoperative intramuscular injection of midazolam (0.05 mg/kg; Jiangsu Enhua Pharmaceutical Co., Xuzhou, China). Subjects in the EGA group underwent epidural puncture at T8 and T9 for instillation of 2% lidocaine (3 mL; Shandong Hualu Pharmaceutical Co., Liaocheng, China) by catheter to confirm epidural analgesia, thus indicating that the epidural block was successful. Patients in both the EGA and SGA groups underwent right internal jugular vein catheterization, and the first blood sample was obtained. Routine monitoring parameters were established, including electrocardiogram (ECG), heart rate, peripheral capillary oxygen saturation (SpO_2), capnography, central temperature, and invasive blood pressure.

As for our anaesthesia protocol, patients were induced with 4 $\mu g/mL$ propofol (B. Braun Melsungen AG, Berlin, Germany, using the Marsh model) and 4 ng/mL remifentanil (Renfu Pharmaceutical Co., Beijing, China) by target-controlled infusion (TCI) (using the Braun Space) to the target plasma concentrations. Intravenous rocuronium (Zhejiang Xianju Pharmaceutical Co., Taizhou, China) was administered at a dose of 0.6 mg/kg. Patients then underwent intubation after about 120 s and were connected to a Dräger Fabius anaesthesia machine (Drägerwerk AG, Lübeck, Germany) for the onset of surgery. Anaesthesia was maintained with sevoflurane [Dräger AbbVie; minimal alveolar concentration (MAC), 0.8–1.2]. Patients in the EGA group were given a loading dose of 0.375% ropivacaine (10 mL; NAROPIN, AstraZeneca Pharmaceutical Co., Wuxi, China), 2 mg of morphine administered epidurally before the incision, and then 0.375% ropivacaine (4–5 mL) administered to maintain the epidural block every hour depending on the height and weight of the patient. Patients in the SGA group were given intravenous sufentanil (Renfu Pharmaceutical Co.) by TCI at a plasma concentration of 0.2–0.8 ng/mL, and the plasma concentration was set based on the haemodynamics and surgical procedure. The arterial blood pressure and heart rate fluctuations in both groups are

controlled under 20%. Sufentanil TCI was stopped 30 min before the surgery ended. Before extubation, ramosetron was used for preventing postoperative nausea and vomiting (PONV). After extubation, all patients were monitored in the post-anaesthesia care unit for at least 50 min.

Postoperative analgesia

For patients in the EGA group, PCEA was administered using an electronic analgesia pump (Apon ZZB-300, Nantong, China). The analgesic drugs included ropivacaine (0.12%) and morphine (0.02 mg/mL), which were diluted in 0.9% normal saline to a final volume of 250 mL. The analgesia pump settings were as follows: background dose of 3 mL/h, bolus volume of 4 mL for each PCA aliquot and a lockout interval of 8 min. For patients in the SGA group, the PCIA pump contained sufentanil (1 µg/mL) and ramosetron (0.6 mg in total), which were administered via the jugular vein catheter. The pump had a total volume of 250 mL, a background dose of 0.03 mL/kg, a bolus volume of 5 mL, and a lockout interval of 8 min. The PCA pumps were removed 48 h after surgery. All patients were followed up on postoperative day (POD)0, POD1, and POD2 using a visual analogue scale (VAS) to evaluate their pain levels. Side effects, including PONV, urinary retention, pruritus, and respiratory depression, were also recorded after surgery.

Baseline and operative characteristics

The following baseline demographic and clinical characteristics were collected: age, sex, Child-Pugh score, and presence/absence of hepatitis. The following intraoperative characteristics were recorded: operation time, blood loss, and use of norepinephrine. The following postoperative characteristics were collected: postoperative pathological diagnosis; size, number, and stage of tumours; and length of hospital stay.

Study outcomes

IFN- γ , interleukin (IL)-4, and transforming growth factor (TGF)- β_1 are considered to be the typical cytokines produced by Th1, Th2, and Treg cells, respectively. The primary study outcome was the plasma concentrations of IL-4/IFN- γ [baseline/before surgery (T_0) and 24 h after surgery (T_3)] because IFN- γ and IL-4 are most upregulated at T_3 (20).

The secondary outcomes were the plasma concentrations of cortisol, tumour necrosis factor (TNF)- α , IL-6 [T_0 and 1 h after surgery (T_2)], glucose [T_0 , 5 min after portal block release (T_1), and T_2], IL-4, IFN- γ , and TGF- β_1 (T_0 and T_3); the proportions of circulating CD3⁺, CD4⁺, CD8⁺, CD4⁺/CD8⁺ T cells, NK cells, and B cells [T_0 , T_3 , and on a POD5 (T_4)]; the VAS scores, assessed at POD0, POD1, and POD2, both at rest and during active coughing; and length of hospital stay; the determination of 3-month and 1-year recurrence and mortality rates.

Blood samples and follow-up

Plasma was sampled at five-time points (T_0 , T_1 , T_2 , T_3 , and T_4 ; *Figure 1*). At each time point, peripheral blood (30 mL in total) was drawn into ethylenediamine tetraacetic acid (EDTA)-spiked tubes and immediately transferred to the hospital laboratory for analysis of cortisol, IL-6, TNF- α and circulating immune cell levels. The plasma cortisol level was measured by radioimmunoassay, and circulating immune cell counts were measured by flow cytometry. For IFN- γ , IL-4, and TGF- β_1 analysis, the samples were centrifuged and stored at -80 °C for use in the enzyme-linked immunosorbent assay. Patients were required to take routine test for surveillance, respecting ultrasound, tumour markers or computed tomography (CT)/MRI in 1 month, 3 months and 1 year after surgery. Telephone follow-up was used to determine patients' survival.

Sample size calculation

The study was a non-inferiority RCT, designed to investigate whether the effect of Th cell subsets (IFN- γ /IL-4) in the SGA group at T_3 was comparable to the EGA group. In a previous study, IFN- γ /IL-4 was {mean [standard deviation (SD)], 1.39 (1.00)} at T_3 for patients undergoing general anaesthesia, and [mean (SD), 1.75 (2.27)] at T_3 for epidural anaesthesia combined with general anaesthesia (22). We chose the non-inferiority margin (δ) as 0.35. NCSS-PASS 11 software (NCSS, Kaysville, UT, USA) was used to select the method of non-inferiority test for the mean of two independent samples, and $\alpha=0.05$ and $1 - \beta=0.8$ were set. The ratio of sample size in the two groups was 1:1, and the calculated sample size was 77 in each group, giving a total of 154. Considering missing samples, we added a 10% loss of follow-up rate, giving a final sample size of each group of 85, for a total of 170.

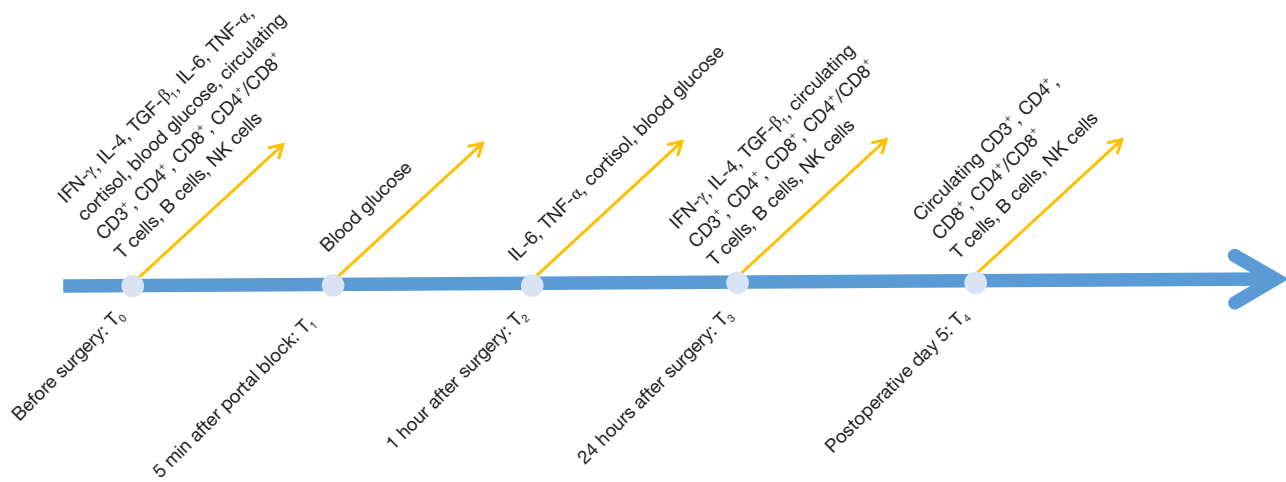

Figure 1 Sample acquisition timeline. The five time points are shown as white dots. The parameters assessed at each time point are indicated. IFN, interferon; IL, interleukin; TGF, transforming growth factor; TNF, tumour necrosis factor; NK, natural killer.

Statistical analysis

Statistical analyses were performed with SPSS 26.0 software (SPSS, Chicago, IL, USA). Continuous variables with normal distributions are presented as mean (SD) and compared by independent samples *t*-tests. Continuous variables with abnormally distributed data are presented as median [interquartile range (IQR)] and compared by the nonparametric Mann-Whitney *U*-test. Categorical variables are presented as numbers with percentages (%) and compared by the χ^2 test. $P < 0.05$ (two-side test) indicated statistical significance.

Results

Patients characteristics

Between October 2020 and February 2022, 180 patients were screened and 170 were ultimately included in the study. The CONSORT flow diagram (Figure 2) shows the details of patient assessment and exclusion. Tables 1,2 give an overview of the patients' baseline characteristics and operative information, including age, sex, body mass index (BMI), tumour size, Barcelona Clinic Liver Cancer (BCLC) stage, preoperative liver cirrhosis, herpesvirus B infection, surgery-related factors, intensive care unit (ICU) stay, and hospital stay. The final diagnoses were confirmed by postoperative histological analyses. Among the 162 patients who underwent open hepatectomy and were analysed, 139 (85.8%) were diagnosed with HCC, 4 (2.5%) were

diagnosed with intrahepatic cholangiocellular carcinoma (ICC), 5 (3.1%) were diagnosed with focal nodular hyperplasia (FNH), and 14 (8.6%) were diagnosed with other hepatic diseases (based on inflammatory changes). We compared the postoperative treatments for HCC patients, including transarterial chemoembolization, targeted therapy or none. No differences were found between the two groups (Table 2).

Plasma concentrations of IFN- γ , IL-4, and TGF- β_1

As shown in Figure 3 and Table 3, no significant differences in the plasma concentrations of IFN- γ , IL-4, IFN- γ /IL-4, and TGF- β_1 were observed between the groups. In the two groups, the plasma concentrations of IL-4 and IFN- γ were increased slightly at T_3 compared with the baseline values (T_0). The IFN- γ /IL-4 ratio remained comparable between the two groups at T_3 [median (IQR), 20.78 (12.73–29.18) vs. 19.52 (13.98–29.29), $P = 0.607$]. The plasma concentration of TGF- β_1 in the SGA group was increased and comparable to that of T_3 in the EGA groups [median (IQR), 228.01 (61.33–372.48) vs. 238.01 (65.18–303.67) pg/mL, $P = 0.748$].

Circulating immune cells

As shown in Figure 4 and Table 4, the circulating levels of CD3 $^+$, CD4 $^+$, CD8 $^+$, and CD4 $^+$ /CD8 $^+$ T cells were all decreased on POD1, but those of CD3 $^+$ and CD4 $^+$ T cells nearly recovered to baseline values at T_4 in both groups; the

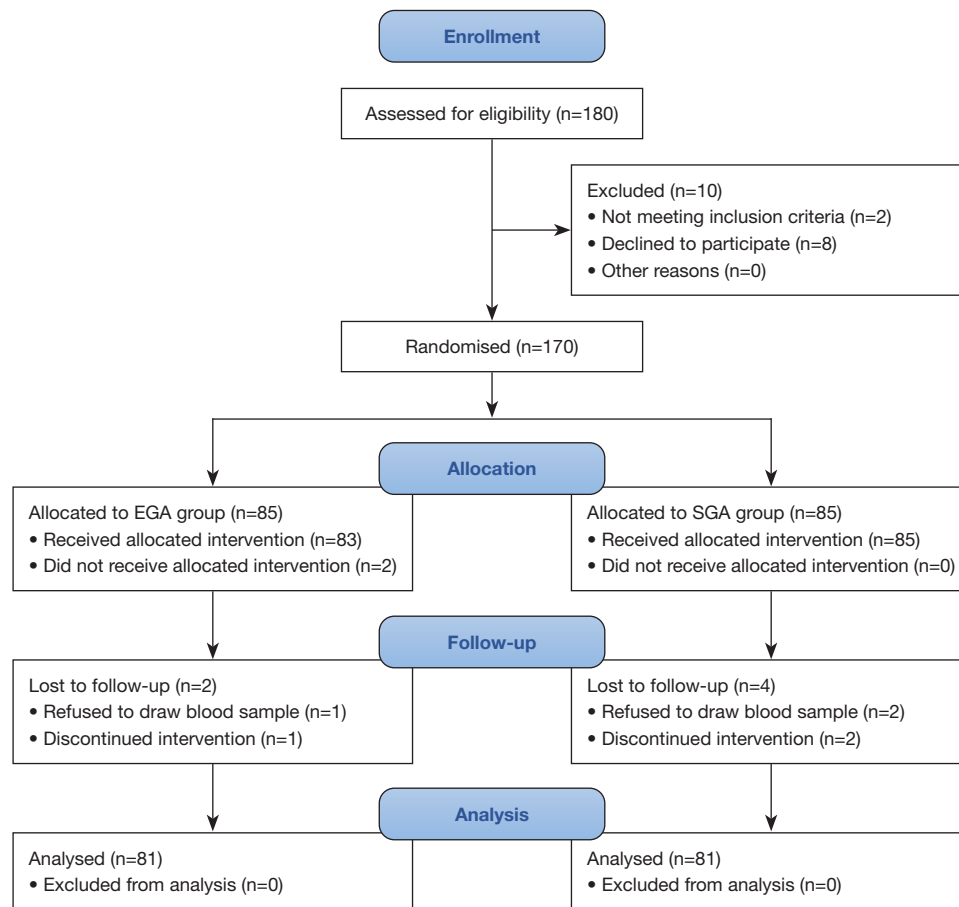

Figure 2 Study flow chart (CONSORT diagram). EGA, general anaesthesia combined with epidural anaesthesia; SGA, general anaesthesia combined with sufentanil target-controlled infusion.

ranges at T_4 were comparable between the two groups. The $CD4^+/CD8^+$ ratio was also comparable between groups at T_4 [median (IQR), 1.80 (1.40–2.30) vs. 1.70 (1.30–2.40)]. In both groups, the proportion of $CD8^+$ T cells continued to decrease until T_4 . Moreover, as shown in *Figure 4*, the B cell proportion was obviously increased in both groups at T_3 and remained nearly unchanged at T_4 ; the proportions of NK cells were increased on T_3 in both groups and decreased significantly on T_4 . The circulating immune cell levels did not significantly differ between the SGA and EGA groups at T_0 , T_3 , or T_4 .

Plasma concentrations of cortisol, glucose, IL-6, and TNF- α

As shown in *Figure 5* and *Table 5*, the plasma levels of TNF- α at T_2 were significantly higher in the SGA group

than in the EGA group [median (IQR), 7.45 (6.20–9.80) vs. 5.95 (4.95–7.45) pg/mL, $P < 0.001$]. Similarly, the plasma IL-6 and cortisol levels were notably increased in both groups at T_2 but showed comparable ranges. The blood glucose concentrations were remarkably increased in both groups at T_1 compared with those at T_0 and recovered toward the baseline at T_2 .

VAS scores

As shown in *Table 6*, the VAS scores (at rest, and while coughing) of the SGA and EGA groups were not different on POD0. Notably, on POD1 and POD2, significant differences were observed, because more patients suffered moderate pain both at rest and while coughing in the SGA group than in the EGA group.

Table 1 Patients' characteristics

Characteristics	SGA (n=81)	EGA (n=81)	P value
Age (years)	52.48 (1.10)	53.20 (1.00)	–
Sex (male/female)	71 (87.7)	70 (86.4)	–
BMI (kg/m ²)	24.05 (2.91)	23.46 (2.97)	–

Recurrence, metastasis and survival

In this perspective cohort, 139 of 162 patients were diagnosed as HCC and included in the 3-month and 1-year follow-up. As shown in *Table 7*, there were 3 (4.5%) HCC recurrence in the SGA group and 4 (5.5%) in the

Table 7 Cancer recurrence and survival in 3-month and 1-year follow-up

Parameters	SGA (n=66)	EGA (n=73)	P value
3-month			
Recurrence (y/n)	3 (4.5)	4 (5.5)	0.801
Metastasis (y/n)	0 (0.0)	0 (0.0)	–
Death (y/n)	1 (1.5)	0 (0.0)	0.291
1-year			
Recurrence (y/n)	10 (15.2)	14 (19.2)	0.531
Metastasis (y/n)	2 (3.0)	1 (1.4)	0.501
Death (y/n)	1 (1.5)	0 (0.0)	0.291

Data are expressed as n (%). SGA, general anaesthesia combined with sufentanil target-controlled infusion group; EGA, general anaesthesia combined with epidural anaesthesia group; y/n, yes/no.

EGA group; one patient in the SGA group died during the 3-month follow-up period, but none in the EGA group. In the 1-year follow-up, there were 10 cases of recurrence in the SGA group and 14 in the EGA group. As for HCC metastasis, there were 2 (3.0%) in SGA, 1 for

lung metastasis, 1 for bone metastasis, 1 (1.4%) was found in EGA (lung metastasis). No significant difference was found in either short- or long-term follow-up for HCC recurrence, metastasis and survival in both groups.

Discussion

Surgery is the mainstay treatment for patients with hepatic carcinoma. In addition to the surgical technique and (neo) adjuvant therapies, anaesthesia- and analgesia-related factors have attracted increasing attention due to their potential influence on postoperative outcomes (5,18). Our current study showed that the effect of perioperative intravenous opioids on the postoperative immune response was comparable to that of epidural anaesthesia.

Systemic immune responses to surgical stress include increased tumour-promoting Treg and Th2 cell counts as well as decreases in both the numbers and capacities of NK cells (innate immune system) and cytotoxic CD8⁺ T cells (adaptive immune system) (23,24). These alterations have been shown to increase the risk of cancer recurrence in both animal models (25-27) and a variety of tumour types in clinical scenarios (28). Furthermore, patients with advanced cancer have a Th2-dominant status (29). IFN- γ and IL-4 are cytokines produced by Th1 and Th2 cells, respectively (30). In the current study, the IFN- γ /IL-4 ratio was used to represent the Th1/Th2 balance (31-34). Although spinal anaesthesia with sevoflurane was shown to preserve IFN- γ /IL-4, whereas sevoflurane alone significantly reduced IFN- γ /IL-4 under laparotomy conditions in mice (30), our results showed that the IL-4 and IFN- γ levels as well as the IFN- γ /IL-4 ratio were comparable between the SGA and EGA groups on POD1, which indicated intravenous opioids did not further worsen the balance of Th1/Th2 cells. Unlike in the animal studies, sufentanil was administered systemically in our study which could partly explain the different results.

Compared with morphine, fentanyl and related agents are more effective at modifying the hormonal responses to surgery. TCI of opioids has been shown to improve intraoperative hemodynamic stability and decrease the intraoperative opioid requirements (35). TCI of sufentanil, even over a long period, has demonstrated predictive pharmacokinetic accuracy (36).

Cumulative evidence from retrospective and preclinical research shows that interventions used to modulate the sympathetic nervous system and hypothalamus-pituitary-adrenal (HPA) axis are helpful to reduce cancer recurrence.

Systemic opioids are a vital part of the analgesic component of anaesthesia. Opioids modulate nociception at several levels of neuraxis and centrally mediated neuroendocrine responses to reduce the surgical stress response. Epidural blocks are also an effective sympathetic blockade strategy and attenuate immunosuppression when used in combination with general anaesthesia. In the current study, the levels of blood glucose and plasma cortisol, IL-6 and TNF- α were used to assess the intraoperative stress response. The levels of glucose, cortisol and IL-6 were comparable between the two groups, while the levels of TNF- α were significantly higher in the SGA group than that in the EGA group. The nervous system branches as an extension of the circulatory system, and peripheral nerve-driven neurotransmitters regulate the progression of diverse cancers (37). In addition to stress effects on tumours, the activation of sympathetic nerves promotes the metastasis of solid tumours by other mechanisms, including inflammation (38). Further studies should be performed to assess the effect of increased IL-6 and TNF- α levels on tumour progression.

Poorly controlled pain may drive malignant processes, possibly due to the increased activity of the sympathetic system and HPA axis, and the subsequent increases in catecholamine and glucocorticoid levels suppress the immune system (38). In addition to systemic opioids, postoperative epidural analgesia is recommended for patients undergoing upper abdominal and thoracic surgeries. Our study focused on perioperative immune changes after two anaesthesia strategies and compared the effectiveness of postoperative analgesics. Patients in both groups reported comparable pain control both at rest and while coughing on POD1, but patients in the EGA group reported better pain relief on POD2.

NK cells are key participants in effective tumour immunosurveillance, and the TGF- β_1 cytokine is produced by Treg cells and correlates with reduced patient survival and recurrence-free rates (20). In an animal study, TGF- β_1 was shown to promote Treg cell differentiation and was identified as an inhibitory mechanism of CD8⁺ T cells (39), which play opposing roles in antitumour surveillance (20). In a recent single-cell RNA sequencing (scRNA-seq) study, early-relapse tumours exhibited increased CD8⁺ T cell infiltration (40), and circulating CD4⁺ T cells are independent predictors of disease-free survival and overall survival after HCC resection (41). In this study, the TGF- β_1 levels and numbers of postoperative NK and CD3⁺, CD4⁺, and CD8 T cells did not significantly differ between the

two groups. The numbers of B lymphocytes (CD19⁺) were also comparable between the two groups.

Compared with epidural blockade, systemic opioids have more severe effects on immune functions, including attenuating innate immunity by inhibiting NK cytotoxicity and activating the HPA axis, consequentially resulting in immunosuppression (17,42). However, different opioids have different effects on NK cell cytotoxicity (17). In addition, NK cell cytotoxicity-related cancer outcomes have not been assessed in human clinical settings. Opioid receptors are reported to be expressed in cancer cells, thereby enabling the opioid-related stimulation of tumorigenic processes, including migration, angiogenesis, and metastasis (43). In clinical retrospective studies, conflicts exist regarding the influence of systemically used opioids on metastasis (18). Retrospective studies on the effect of neuraxial blockade also report mixed results regarding overall survival (17). Patients receiving abdominal surgery for cancer resection were randomized to receive either epidural analgesia or postoperative systemic morphine analgesia, with no difference in cancer recurrence and mortality rates at 2–3 years in either group (44). A prospective cohort study of 34,188 cancer survivors who had had surgery for early breast cancer showed that opioids were not associated with cancer recurrence (45). In a recent RCT on breast cancer, there was no difference in cancer recurrence rates between patients receiving regional anaesthesia analgesia and systemic opioids (46).

Some limitations of this study should be mentioned. The subjects of the study were mainly male patients, as HCC occurs more in male than female patients (with a 10:1 male-to-female ratio). Therefore, the results may not be representative of the whole population and other types of cancer. Second, the study was a single-site study with a small sample size. Third, IFN- γ /IL-4 (Th1/Th2) was designed as the primary outcome in this prospective study, while studies focused on patients' survival and prognosis outcomes should also be carried out, therefore, bigger size and multiple-site studies should be designed. Also, we mainly focused on T cell subsets and other immune factors, as the immune system was far more complex, and other factors need to be detected and investigated in the future.

Conclusions

Our results showed that although the proinflammatory factor TNF- α was expressed at higher levels in the SGA group than in the EGA group, the tumour-related immune

responses were comparable between the two groups. More importantly, the short- and long-term follow-ups showed no difference between groups in liver cancer recurrence and survival rate. SGA appears not to be inferior to EGA regarding tumour-related immunity and prognosis. Intravenous opioid use appears not to be inferior to epidural anaesthesia, and can be used safely in HCC patients without worsening patients' prognosis.
