ABSTRACT: During long-term storage of the liquid propellant  $N_2O_4$ , it absorbs  $H_2O$  to form the  $N_2O_4(H_2O)$ <sub>n</sub> system, and this in turn generates  $HNO_3$ ,  $HNO_2$ , and other substances in the storage tank because of corrosion, which seriously affects the performance of weaponry. In this work, we carried out computational simulations of  $N_2O_4$  with different masses of water based on ReaxFF, analyzed the reaction intermediates and products, and investigated the mechanism of the reaction of  $N_2O_4$  with  $H_2O$ and of  $N_2O_4(H_2O)$ <sub>n</sub>. The results show that the reaction product  $\omega(HNO_3+HNO_2)$  undergoes a rapid growth in the early stage of the reaction and then tends toward dynamic equilibrium; the potential energy of the system decreases with the increase of  $\omega(H, O)$ , the reaction rate increases, and the rate of decomposition of HNO<sub>2</sub> to form HNO<sub>3</sub> increases. When  $\omega(H_2O)$  is 0.2 or 1.0%, the intermediate products are  $N_2O_4H_2O$  or  $N_2O_4(H_2O)_2$ , respectively, and the reaction proceeds along two paths; when  $\omega(H_2O) \geq 2.0\%$ , N<sub>2</sub>O<sub>4</sub>(H<sub>2</sub>O)<sub>3</sub> appears as the intermediate product, HNO<sub>3</sub> and HNO<sub>2</sub> are directly produced in one step, and a stable current loop can be formed within the whole system.

# **1. INTRODUCTION**

 $N_2O_4$  is often used as an oxidizer in two-component liquid propulsion systems in the first and second stages of launch vehicles, owing to its high density, high specific impulse, and strong oxidizing properties.<sup>[1](#page-6-0)</sup> In the case of long-term storage,  $N_2O_4$  absorbs  $H_2O$  from the surrounding environment to form the  $N_2O_4(H_2O)_n$  system, which in turn generates  $HNO_3$ ,  $HNO<sub>2</sub>$ , and other substances, accelerating the corrosion of the storage tank and causing structural damages and propellant leakage, which are hazardous and threaten the safety of the equipment. $\frac{2}{3}$  Therefore, the study of the reaction mechanism of  $N_2O_4$  and  $H_2O$  is of great significance for the structural design of weapons and equipment as well as for long-term storage safety.

At present, the test and analysis methods for  $N_2O_4$  are mainly based on the Chinese military standard GJB1673−93; further, owing to the limitation of the instruments, the accuracy of test results is poor, and only parameters such as the equivalent water content of  $N_2O_4$  with a water content of ≤0.4% can be determined, whereas determination of the content of  $HNO<sub>3</sub>$ ,  $HNO<sub>2</sub>$ , and other substances is impossible. In addition,  $N_2O_4$  is a volatile, reddish-brown transparent liquid at room temperature with strong oxidizing and toxic properties.<sup>[3](#page-6-0)</sup> Therefore, the design and performance of the experiments are challenging.

In principle, quantum chemistry (QC) is applicable to all chemical systems but not to large systems owing to the high computational effort.<sup>[4](#page-6-0)</sup> Although conventional force fields such as  $\overline{M}M3$ ,<sup>[5](#page-6-0),[6](#page-6-0)</sup> DREIDING,<sup>[7](#page-6-0)</sup> and EFF<sup>[8](#page-6-0)</sup> can be applied in the case of large systems, they can only describe the interactions

between molecules and those within condensed phase systems. ReaxFF is a bond order-based reaction force field, originally proposed by van Duin in 2001, that has no energy or force discontinuities, even during a reaction. $9$  Thus, ReaxFF can describe the formation and dissociation of chemical bonds. The classical treatment of reactive chemistry made available by the ReaxFF method has enabled numerous studies of phenomena occurring on scales that were previously inaccessible via computational methods. In particular, ReaxFF is capable of modeling reaction events involving reactions at the interface between the solid, liquid, and gas phases, which is possible because the ReaxFF description of each element can be transferred across phases. For example, the same system of mathematical forms is used for an oxygen atom, whether that oxygen is in the gas phase as  $O_2$ , in the liquid phase within an H2O molecule, or bound in a solid oxide. This transferability coupled with lower computational costs that allow for longer simulation time scales enables ReaxFF to consider phenomena that depend not only on the reactivity of the species involved but also on dynamic factors such as diffusivity and solubility that affect how species migrate through the system. This allows ReaxFF to model complex processes involving multiple stages in contact with each other.<sup>[10](#page-6-0)</sup> Zhao<sup>[11](#page-6-0)</sup> and Liu<sup>[12](#page-7-0)</sup> et al. simulated

<span id="page-1-0"></span>the combustion and explosion of  $N_2O_4$  and combustant based on the ReaxFF molecular dynamics simulation method, but the system remains in a state of rapid warming and long-term maintenance of the high temperatures. At present, few studies have focused on the reaction mechanism of  $N_2O_4$  with  $H_2O$ , and these were mainly based on the density functional theory  $(DFT)$  to explore the isomerization and reaction process.<sup>13−2</sup> Only a limited number of tests have been performed by  $AFRPL<sup>25</sup>$  which is not enough to perfect the reaction path.

In this study, ReaxFF molecular dynamics simulation was used to simulate the intermediates and products of the reaction of  $N_2O_4$  with different mass fractions of  $H_2O$ , and combined with the results of the previous work of the group, the reaction course of the  $N_2O_4(H_2O)$ <sub>n</sub> system was investigated based on DFT, to analyze the reaction mechanism between  $N_2O_4$  and  $H<sub>2</sub>O$  at room temperature.

# **2. COMPUTATIONAL METHOD**

Molecular dynamics studies of N<sub>2</sub>O<sub>4</sub> and H<sub>2</sub>O ( $\omega$  = 0.2–8%) were based on the results of Brown C.T. $^{25}$  $^{25}$  $^{25}$  and the Chinese military standard GJB1673–93. The mixing ratios of  $N_2O_4$  and  $H<sub>2</sub>O$  are shown in Table 1. The initial configurations of  $N<sub>2</sub>O<sub>4</sub>$ 

Table 1. Mixing Ratio of  $N_2O_4$  to  $H_2O$ 

and  $H_2O$  were optimized using Materials Studio software.<sup>26</sup> The initial reactants were randomly inserted into the simulation box, and then, the periodic system was constructed using the amorphous cell module. A conjugate gradient method was adopted for the initial system to perform energy minimization calculations, which facilitate the subsequent relaxation operation. According to the conclusions of Miller,  $14$  $N_2O_4$  and  $H_2O$  were subjected to 90 ps isothermal isotropic (NVT) kinetic equilibrium with a step size of 0.3 fs at a temperature of 293 K. Temperature control was achieved using the Berendsen method with a temperature damping coefficient of 0.1 ps. Atomic and molecular species and dynamic trajectories were determined every 100 steps. All MD simulations were performed in the Lammps package<sup>27</sup> using the ReaxFF method.<sup>28</sup> In order to verify the reaction products, the polarization curves for a model Al alloy in  $N_2O_4$  with different *ω*(H<sub>2</sub>O) values were tested. Further, the reaction process of N2O4 with different *ω*(H2O) was explored in conjunction with the previous work of the group.<sup>2</sup>

# **3. RESULTS AND DISCUSSION**

**3.1. Reaction Products HNO<sub>3</sub> and HNO<sub>2</sub>.** According to the conclusions of  $Liu$ ,<sup>[1,2](#page-6-0)</sup> the main corrosive intermediates generated by the reaction of  $N_2O_4$  with  $H_2O$  are HNO<sub>3</sub> and  $HNO<sub>2</sub>$ , and their mass fractions depending on the  $H<sub>2</sub>O$ amount reacting with  $N_2O_4$  are shown in Figure 1. In the initial stage of the reaction,  $\omega(HNO_3+HNO_2)$  rapidly increases, and then, its mass fraction is gradually stabilized, reaching dynamic equilibrium, with a further increase in the amount of formed products in the system. In order to verify the corrosion intensity of  $H_2O$ -containing  $N_2O_4$ , a certain type of aluminum alloy was selected to carry out the polarization curve test, the results of which are shown in [Figure](#page-2-0) 2. The electrochemical

Figure 1.  $\omega$ (HNO<sub>3</sub>+HNO<sub>2</sub>) during the reaction of N<sub>2</sub>O<sub>4</sub> with different  $\omega$ (H<sub>2</sub>O).

corrosion current densities obtained from the fitting are listed in [Table](#page-2-0) 2. When  $\omega(H_2O)$  < 1.0%, the measured polarization curves were extremely unstable, and no obvious equilibrium electrode potential appeared. As shown in Figure 1, the least amount of  $HNO<sub>3</sub> + HNO<sub>2</sub>$  was generated. Since  $N<sub>2</sub>O<sub>4</sub>$  is not conductive, this also led to an uneven distribution of the generated ions in the solution, which were in a free state and could not form a stable current loop. With the increase in  $\omega(H_2O)$ , the number of ions generated within the  $N_2O_4(H_2O)_n$  system gradually increased, and as shown in [Figure](#page-2-0) 2,  $\omega(H_2O) = 1.0\%$  is the detection limit using the polarization curve. When  $\omega(H_2O) > 1.0\%$ , the polarization curve tends to be regular, indicating that a sufficient number of ions exist within the solution to form a stable current loop. Further, when  $\omega(H_2O) > 2.0\%$ , as shown in [Table](#page-2-0) 2, the corrosion current density changes abruptly, and its corresponding polarization curve is compared to  $\omega(H_2O) = 2.0\%$ . Further, a significant passivation area and pitting potential  $E<sub>b</sub>$  of about 0.3 V, combined with the results in Figure 1, indicate that passivation occurs on the surface of the specimen when  $\omega(H_2O)$  > 2.0%, while the dissolution film formation equilibrium reaction occurs at a higher corrosion rate.

Based on the results in Figures 1 and [2,](#page-2-0) the changes in the potential energy  $(\Delta E_p)$  during the reaction of N<sub>2</sub>O<sub>4</sub> with  $\omega(H_2O) = 0.2, 1.0, 2.0,$  and 6.0% were analyzed as shown in [Figure](#page-2-0) 3, with the unit au/atom meaning the total potential energy of the system divided by the total number of atoms. When  $N_2O_4$  comes into contact with H<sub>2</sub>O, the potential energy of the whole system decreases dramatically, and an exothermic chemical reaction occurs. Subsequently, the generated  $HNO<sub>2</sub>$  absorbs heat and undergoes decomposition that leads to a rise in the potential energy of the system; eventually, when the reaction equilibrium is reached in the system, its potential energy also reaches a stable state. Moreover, with the increase in  $\omega(H_2O)$ , the potential energy of the system decreases, the rate of decrease is the highest in the initial stage, and the final equilibrium state is also lower, which indicates that the reaction rate is faster, and the energy released is also larger.

[Figure](#page-3-0) 4 shows the variation in the amount of  $HNO<sub>3</sub>$  and  $HNO<sub>2</sub>$  during the course of the reaction between  $N<sub>2</sub>O<sub>4</sub>$  and different  $\omega(H_2O)$ . As shown in [Figure](#page-3-0) 4, the production of  $HNO<sub>2</sub>$  can be roughly divided into three phases: a period of

<span id="page-2-0"></span>

Figure 2. Polarization curves of the type XX aluminum alloy for the reaction of different  $\omega(H_2O)$  ions with N<sub>2</sub>O<sub>4</sub>.

Table 2. Corrosion Current Density of the Type XX Aluminum Alloy for the Reaction of Different  $\omega(H_2O)$  with N<sub>2</sub>O<sub>4</sub>

Figure 3. Potential energy changes for the reaction of different amounts of  $H_2O$  with  $N_2O_4$ .

rapid increase in the amount of  $HNO<sub>2</sub>$  produced, a period of slow decrease in the amount of  $HNO<sub>2</sub>$  produced, and a stabilization period; on the other hand, the production of  $HNO<sub>3</sub>$  has only a period of gradual increase in the amount of  $HNO<sub>3</sub>$  produced and a stabilization period. In the early stage of the reaction, the production rate and quantity of  $HNO<sub>2</sub>$  are higher than that of  $\mathrm{HNO}_{3}$ , but as the reaction proceeds,  $\mathrm{HNO}_{2}$ is further decomposed into  $HNO_3$  and  $NO: 3HNO_2 \rightarrow HNO_3$  $+ 2NO + H<sub>2</sub>O$ .

Consistent with the conclusions of AFRPL,<sup>25</sup> when  $\omega(H_2O)$ = 0.2%, the amount of  $HNO<sub>3</sub>$  and  $HNO<sub>2</sub>$  is almost the same after the reaction is stabilized. When  $\omega(H_2O)$  is increased, the yield of  $HNO<sub>2</sub>$  always remains low because the decomposition of HNO<sub>2</sub> produces H<sub>2</sub>O that continues to react with N<sub>2</sub>O<sub>4</sub>:  $N_2O_4 + H_2O \rightarrow HNO_3 + HNO_2$ .

Therefore,  $HNO<sub>2</sub>$  does not decompose completely, and the whole system remains in a dynamic equilibrium. However, the reaction time required for the amount of  $HNO<sub>3</sub>$  to exceed that of  $HNO<sub>2</sub>$  continuously reduces. As shown in Figure 3d, the amount of  $HNO<sub>3</sub>$  generated exceeds that of  $HNO<sub>2</sub>$  at  $T = 1200$ fs, indicating that the reaction rate of the system increases with  $\omega(H_2O)$ , which is also verified by the results of Multer.<sup>14</sup>

**3.2. Intermediate**  $N_2O_4(H_2O)_n$ **.** The reaction between  $N_2O_4$  and  $H_2O$  first produces the  $N_2O_4(H_2O)_n$  complex due to

<span id="page-3-0"></span>

Figure 4. Variation in amount of HNO<sub>3</sub> and HNO<sub>2</sub> during the course of the reaction of N<sub>2</sub>O<sub>4</sub> with different  $\omega(H_2O)$ .

hydrogen bonding, $14$  which further affects the course of the reaction depending on the value of *n*. [16](#page-7-0) Therefore, the intermediates formed with  $\omega(H_2O) = 0.2$ , 1.0, 2.0, and 6.0% were analyzed. [Figure](#page-4-0) 5 shows the mass fraction of the intermediate product  $N_2O_4(H_2O)_n$  for different *ω*(H<sub>2</sub>O). As shown in [Figure](#page-4-0) 5a, at  $\omega(H, O) = 0.2\%$ , the intermediate product is only  $N_2O_4(H_2O)$ , the yield of which increases rapidly and remains stable for a long period of time with the mass fraction maintained at about 0.12%. As  $ω(H, O)$ continues to increase, as shown in [Figure](#page-4-0) 5b, a small amount of  $N_2O_4(H_2O)$ <sub>2</sub> appears, but the main intermediate product is still  $N_2O_4(H_2O)$ . Then, as shown in [Figure](#page-4-0) 5c, the yield of  $N_2O_4(H_2O)$  further increases at  $\omega(H_2O) = 2.0\%$  and the yield of  $N_2O_4(H_2O)$  tends to be stabilized;  $N_2O_4$  combines with  $H<sub>2</sub>O$  in the local region of the system and produces  $N_2O_4(H_2O)_3$ , but the yield of  $N_2O_4(H_2O)_3$  is unstable and low. When  $\omega(H_2O) = 6.0\%$ , the mass percentage of its intermediate product  $N_2O_4(H_2O)_2$  increases dramatically, and

although its yield exceeds that of  $N_2O_4(H_2O)$ , the  $N_2O_4(H_2O)$ content does not change substantially with respect to that corresponding to  $\omega(H_2O) = 2.0\%$ ; this indicates that when  $\omega(H_2O)$  = 6.0%, the N<sub>2</sub>O<sub>4</sub>(H<sub>2</sub>O) content in the system is saturated and that some  $N_2O_4$  would bind more  $H_2O$ . Therefore, the yield of  $N_2O_4(H_2O)_2$  increases dramatically and stabilizes; at the same time, after the system reaches equilibrium, the yield of  $N_2O_4(H_2O)_3$  also tends to stabilize to 1.0%.

**3.3. Reaction Mechanism.** The results of the previous study of this group show that the reaction of one  $N_2O_4$ molecule with different amounts of  $H<sub>2</sub>O$  result in complexes with different structures,<sup>29</sup> as shown in [Figure](#page-5-0) 6. One  $N_2O_4$ molecule combines with one  $H<sub>2</sub>O$  molecule to form  $N_2O_4(H_2O)$ , which has only one stable structure, namely, IM1, as shown in [Figure](#page-5-0) 6a. However, when one  $N_2O_4$ molecule combines with two  $H_2O$  molecules, two structures are formed: two  $H<sub>2</sub>O$  molecules located on the same side of

<span id="page-4-0"></span>

Figure 5. Mass fraction of the reaction intermediate  $N_2O_4(H_2O)$ <sup>n</sup> for the reaction of  $N_2O_4$  with different  $\omega(H_2O)$ .

 $N_2O_4$ , as shown in [Figure](#page-5-0) 6b, and two  $H_2O$  molecules located on both sides of  $N_2O_4$ , as shown in [Figure](#page-5-0) 6c. Similarly, the combination of one  $N_2O_4$  molecule with three  $H_2O$  molecules produces  $N_2O_4(H_2O)_3$  with two structures, i.e., three  $H_2O$ molecules located on the same side of  $N_2O_4$ , as shown in [Figure](#page-5-0) 6d, and two  $H_2O$  molecules on one side of  $N_2O_4$  and one  $H<sub>2</sub>O$  molecule on the other side, as shown in [Figure](#page-5-0) 6e. When  $H_2O$  is located on the same side of  $N_2O_4$ , the number of interconnected chemical bonds is fewer and the bond length is shorter, so the reaction potential energy of IM2 and IM4 is lower and the molecular structure is more stable than those of IM3 and IM5. Thus, in summary,  $N_2O_4$  reacts with  $H_2O$  and its intermediate products are IM1, IM2, and IM4.

After the formation of the intermediate product  $N_2O_4(H_2O)$ <sub>n</sub>, there are usually two alternatives for the next reaction: the direct decomposition of  $N_2O_4(H_2O)_n$  to form  $HNO<sub>3</sub> + HNO<sub>2</sub>$  and the final formation of  $HNO<sub>3</sub> + HNO<sub>2</sub>$ from  $N_2O_4(H_2O)$ <sub>n</sub> after *t*-ONONO<sub>2</sub>- $(H_2O)$ <sub>n</sub>. From [Sections](#page-1-0) [3.1](#page-1-0) and [3.2](#page-2-0), the reaction mechanisms of  $N_2O_4$  with  $\omega(H_2O)$  = 0.2, 1.0, 2.0, and 6.0% are analyzed.

$$
\omega(\text{H}_2\text{O}) = 0.2\% \tag{1}
$$

As can be seen from Figure 5, at  $\omega(H_2O) = 0.2\%$ , the only intermediate product is IM1. The reaction can proceed along both paths simultaneously because the difference between the potential energy surfaces for the two reaction paths of IM1 is small,<sup>[29](#page-7-0)</sup> as shown in [Figure](#page-5-0) 7a: (I) One  $-NO_2$  in IM1 rotates along the N−N bond, which causes the shift of  $H_2O$  and the formation of *t*-ONONO2−H2O. Subsequently, the N1−O4 bond breaks, and  $- NO_3$  and  $- NO_3$  combine with ionized H and  $-OH$  in  $H<sub>2</sub>O$  to form  $HNO<sub>3</sub>$  and  $HNO<sub>2</sub>$ , respectively. (II) IM1 generates  $HNO<sub>3</sub> + HNO<sub>2</sub>$  in one direct step, and the N− N bond in  $N_2O_4$  breaks directly to form two  $-NO_2$ , and one combines with the detached H of  $H_2O$  to form  $HNO_2$ , while the other  $-NO_2$  combines with  $HNO_2$  remaining in  $H_2O$  to form  $HNO<sub>2</sub>$ . NO<sub>2</sub> combines with the remaining −OH in H<sub>2</sub>O to form  $HNO<sub>3</sub>$ .

<span id="page-5-0"></span>

**Figure 6.** Structure of  $N_2O_4(H_2O)$ <sup>n</sup> (*n* = 1–3).

 $\omega(H_2O) = 1.0\%$ (2)

When  $\omega(H_2O) = 1.0\%$ , the main intermediate product of the reaction between  $N_2O_4$  and  $H_2O$  is still IM1, and its main reaction mechanism is the same as that in Figure 7a. However,

a small amount of IM2 appears, and the difference between the potential energy surfaces for the two reaction paths is small. The main reaction paths are shown in Figure 7b: (I) Both of the  $H<sub>2</sub>O$  molecules in IM2 are involved in the reaction course, and *t*-ONONO<sub>2</sub>- $(H_2O)_2$  is in the octameric ring structure. With the further reaction of *t*-ONONO<sub>2</sub>- $(H_2O)_2$ , proton transfer occurs in the two  $H_2O$  molecules during the process; O7 and H10 of one  $H_2O$  (O7) combine with NO to form  $HNO<sub>2</sub>$ , and H12 in the other H<sub>2</sub>O (O10) combines with NO<sub>3</sub> to form  $HNO<sub>3</sub>$ . The remaining H8 and O10 of the two  $H<sub>2</sub>O$ molecules recombine with H11 to form a new  $H_2O$  molecule. (II) Similar to pathway 2 of IM1 in Figure 7a, only one  $H_2O$ molecule is involved in the reaction, which ultimately produces the product directly. Further, the molecule O10 in the other H<sub>2</sub>O interacts with H8 and O7 to form the O–H–O hydrogen bonds. According to Miller et al.,<sup>[14](#page-7-0)</sup>  $t$ -ONONO<sub>2</sub>- $(H_2O)_n$ exhibits equilibrium geometry when  $n \leq 2$ , and the bonding in this molecule is partly ionic but mainly covalent. Therefore, in [Figure](#page-2-0) 2, the polarization curves are not regular for  $\omega(H_2O)$  $\leq$  1.0%, and the solution system cannot form a stable current loop.

$$
\omega(\mathrm{H}_2\mathrm{O}) = 2.0\% \tag{3}
$$

When  $\omega(H_2O) = 2.0\%$ , the main intermediate product is still IM1, but small amounts of IM2 and IM4 are present. The reaction mechanism of IM1 and IM2 is presented in the previous section. According to Miller and previous work,  $14,29$ in  $N_2O_4(H_2O)_n$ , the two-path reaction potential of IM4 reaches 28.4 KJ·mol<sup>-1</sup> at  $n = 3$ , and the reaction rate constant is higher by 2 orders of magnitude compared to that at *n* < 3. Further, the formation of *t*-ONONO<sub>2</sub>- $(H_2O)_2$  is accompanied by proton transfer as the reaction proceeds. Luo et al. $24$ confirmed that hydrogen bonding and a polar environment are prerequisites for intermolecular proton transfer. Moreover, the proton transfer occurring in *t*-ONONO<sub>2</sub> dominates the production of − OH, again supported by experimental <span id="page-6-0"></span>results,<sup>[30](#page-7-0)</sup> leading to an increasingly shorter duration of existence of  $t$ -ONONO<sub>2</sub> as an increasing amount of  $H_2O$  is added. All charge transfer leaps lead to a partial reverse transfer of charge from  $NO<sub>3</sub><sup>-</sup>$  to  $NO<sup>+</sup>$ , which causes difficulty in breaking the ON−ONO2 bond. Therefore, with ionic bonding being predominant in the  $N_2O_4(H_2O)$ <sub>3</sub> system, IM4 can be determined to preferentially cause the direct generation of  $HNO<sub>3</sub>$  and  $HNO<sub>2</sub>$  in one step, as shown in [Figure](#page-5-0) 7c. Therefore, within the solution system, the number of ions reaches a stable value as per the polarization curve.

$$
\omega(\mathrm{H}_2\mathrm{O}) = 6.0\% \tag{4}
$$

When  $\omega(H_2O) = 6.0\%$ , its intermediate product species are the same as those when  $\omega(H_2O) = 2.0\%$ , but the dominant ones are IM1 and IM2; further, the number of IM4 is not negligible and is qualitatively higher than that at  $\omega(H_2O)$  = 2.0%. The dramatic increase in the number of IM4 leads to an enhancement in the corrosion current density by about 2 orders of magnitude and the appearance of passivation regions; these results again validate the experimental results in [Section](#page-1-0) [3.1](#page-1-0). Therefore, the reaction mechanism at  $\omega(H_2O) = 6.0\%$ corresponds to that in [Figure](#page-5-0) 7a−c.

# **4. CONCLUSIONS**

- (1) At the beginning of the reaction, the reaction product  $\omega(\text{HNO}_3 + \text{HNO}_2)$  rapidly increases and then approaches dynamic equilibrium; further,  $ω(H<sub>2</sub>O)$ increases, the potential energy of the system decreases, the rate of the reaction increases, and the rate of decomposition of  $HNO<sub>2</sub>$  to form  $HNO<sub>3</sub>$  increases.
- (2) With  $\omega(H_2O) = 0.2\%$ , one N<sub>2</sub>O<sub>4</sub> molecule combines with only one  $H_2O$  molecule to produce  $N_2O_4·H_2O$ ; as  $\omega(\text{H}_2\text{O})$  increases, small amounts of  $\text{N}_2\text{O}_4(\text{H}_2\text{O})_2$  and  $N_2O_4(H_2O)$ <sub>3</sub> appear as intermediates. At  $\omega(H_2O)$  = 6.0%, the yield of the intermediate product  $N_2O_4(H_2O)_2$ begins to exceed that of  $N_2O_4H_2O$ , and the  $N_2O_4(H_2O)_3$  content reached 1.0%.
- (3) With  $\omega(H_2O) = 0.2$  and 1.0%, the intermediate product  $N_2O_4(H_2O)$ <sub>n</sub> in the system, i.e.,  $N_2O_4(H_2O)$ <sub>n</sub>, reacts along two different paths when  $n = 1$  or 2. When  $\omega(H_2O) \geq 2.0\%$ , the appearance of  $N_2O_4(H_2O)$ <sub>n</sub> in the system tends to produce the final product in one direct step.

#### **Author Contributions**

Y.G.: conceptualization, investigation, methodology, and writing-original draft. G.T.: project administration and validation. X.C.: funding acquisition and writing—review and editing. Z.T.: electrochemical test. Z.H.: data curation and formal analysis. D.L.: resources and supervision. X.Y.: software and validation.

#### **Funding**

This research was funded by the National Natural Science Foundation of China (NO.52272446) and the Natural Science Foundation of Shaanxi Province (NO.2021JM-250).

### **Notes**

The authors declare no competing financial interest.

## ■ **ACKNOWLEDGMENTS**

The authors are very grateful to Associate Researcher Guo Wei and engineers Peng Zheng and Jiang Manzi of the Beijing Institute of Aerospace Testing and Technology, China, for their assistance in this research.
