Long term outcome and quality of life after open incisional hernia repair - light versus heavy weight meshes

Roland Ladurner*, Costanza Chiapponi, Quirin Linhuber and Thomas Mussack

Abstract

Background: Mesh repair of incisional hernia is superior to the conventional technique. From all available materials for open surgery polypropylene (PP) is the most widely used. Development resulted in meshes with larger pore size, decreased mesh surface and lower weight. The aim of this retrospective non randomized study was to compare the quality of life in the long term follow up (> 72 month) after incisional hernia repair with "light weight"(LW) and "heavy weight"(HW) PP meshes.

Methods: 12 patients who underwent midline open incisional hernia repair with a HW-PP mesh (Prolene® 109 g/m² pore size 1.6 mm) between January 1996 and December 1997 were compared with 12 consecutive patients who underwent the same procedure with a LW-PP mesh (Vipro® 54 g/m², pore size 4-5 mm) from January 1998. The standard technique was the sublay mesh-plasty with the retromuscular positioning of the mesh. The two groups were equal in BMI, age, gender and hernia size. Patients were routinely seen back in the clinic.

Results: In the long term run (mean follow up 112 ± 22 months) patients of the HW mesh group revealed no significant difference in the SF-36 Health Survey domains compared to the LW group (mean follow up 75 ± 16 months).

Conclusions: In this study the health related quality of life based on the SF 36 survey after open incisional hernia repair with light or heavy weight meshes is not related to the mesh type in the long term follow up.

Keywords: incisional hernia repair, heavy weight, low weight polypropylene mesh, quality of life

Background

Hernia repair is one of the most common surgical operations with more than 50.000 incisional hernia repaired every year in Germany. Patient seek surgical repair because of physical discomfort and aesthetic reasons. Both impair their quality of life. Unfortunately some patients complain of abdominal discomfort also after the operation. Despite the surgical technique one possible factor is the type of mesh used. Polypropylene (PP) is the most widely used mesh material for hernia repair. PP meshes show a high stretch and tensile strength, five times higher than the maximal physiologic stress. The extent of the scar tissue induced by the mesh depends on the amount and structure of the

incorporated material and is responsible for the abdominal wall compliance [1,2]. In 20% of the cases heavy weight (HW) and small pore size PP meshes caused a reduction of the abdominal wall mobility ("stiff abdomen") [3,4]. This complication was associated with chronic abdominal pain. As a consequence macropore light weight (LW) PP meshes strong enough to resist maximal physiologic stress of the abdominal wall were developed [5]. This development resulted in a reduction of the chronic pain [1,6,7]. Whether macropore LW-PP meshes have also a beneficial effect on the life quality of patients in the long term outcome after open incisional hernia repair is still unclear. The objective of this study was therefore to assess the health related quality of life (HrQoL) and the long term outcome of patients with open incisional hernia repair using HW- versus LW-PP meshes.

Methods

Characteristics of the study group

33 patients with midline open incisional hernias were operated with a heavy weight mesh (Prolene® 108.5 g/m² pore size 1.6 mm, Ethicon, Nordersted; Germany) between January 1996 and December 1997 and were eligible for this study. Unfortunately only 12 of them could be followed up over the years. For the comparison the next 12 consecutive patients operated with a light weight mesh (Vipro® 54 g/m², pore size 4-5 mm, Ethicon, Nordersted, Germany) after January 1998 were enrolled in the study. We excluded incarcerated, lateral or parastomal hernias, hernia repair not using mesh replacement and hernia repair performed with another procedure (laparoscopic hernia repair, onlay and inlay mesh-plasty).

The standard technique consisted of laparotomy, adhaesiolysis, hernia sac resection, closure of the posterior rectus fascia and retromuscular positioning of the PP mesh. Mesh size was chosen so that the margin extended beyond the margin of the defect throughout the defect's entire circumference. The mesh overlap was at least 5 cm. Mesh fixation was performed with interrupted PP 3/0 sutures in the midline and at the border of the mesh. The lateral mesh fixation occurred along the margin of the rectus muscle. By doing this the intercostal nerve branches were carefully preserved to avoid muscular atrophy. The anterior rectus sheath was closed with a continuous PDS 2/0 running suture loop.

Patients were routinely seen back in the clinic 3, 6 and 12 months postoperatively, then yearly thereafter. The standard follow up consisted of anamnesis, physical examination and ultrasound or MRI, when needed (anamnesis and physical examination suggestive of hernia recurrence or intestinal adhesions). The follow up could be completed in all 24 cases.

Life Quality (SF36)

We used the SF-36, a multidimensional questionnaire composed of 36 items to determine the health related quality of life [8]. The SF36 health survey consists of eight different health quality domains: physical function (10 items), role limitations due to physical functions role (4 items), bodily pain (2 items), general health (5 items), vitality (4 items), social function (2 items), role limitations due to emotional function (3 items), mental health (5 items). The results from each scale vary from 0 to 100 (worst to best possible health status). Additionally, the SF-36 Physical Component Summary (PCS), and the Mental Component Summary (MCS) scales were determined, ranging from zero (lowest well-being) to 100 (highest well-being) [9,10]. The SF 36 Health survey scores were compared with the age-stratified

German population. The questionnaire evaluates the negative health aspects (disease or illness) and the positive aspects (well being). The generic SF-36 was chosen instead of more specific scales like the CCS (Carolina Comfort Scale) [11] because it is the gold standard for measuring quality of life and it is validated in German language [12].

Statistical analysis

All data are presented as means and standard deviation. Differences between the intervention groups (HW vs LW PP meshes) were tested for significance using the unpaired t test for quantitative parametric variables and the Mann-Whitney rank sum test for quantitative non parametric variables. The comparisons were performed using STATVIEW 4.5 software (Abacus Concepts, Berkeley, CA). Significance levels were set as p < 0.05.

Results

Patient characteristics

12 patients (mean age 57.3 ± 11.8, range 24-80 years) underwent sublay hernia repair with HW-PP meshes between January 1996 and December 1997. The body mass index (BMI) was 29.8 ± 3.7 kg/m² and the hernia size was 127.2 ± 97.2 cm². From January 1998 all patients received sublay hernia repair with a LW PP mesh. 12 consecutive patients (mean age 58.3 ± 11.1 years, range 28-82 years) were enrolled in the survey. The body mass index (BMI) was 28.7 ± 3.5 kg/m² and the hernia size 226 ± 301.5 cm². The point plot graph shows the hernia size of the two groups (Figure 1).

There were no significant difference in age, gender, body mass index, hernia size, patient related risk factors, operation time and the length of the hospital stay (Table 1). As patient related risk factors were considered obesity (BMI > 30 kg/m²), diabetes mellitus, steroid therapy, nutritional deficiencies, renal impairment, chemotherapy, smoking, chest problems and hepatic cirrhosis [13]. Comorbidities were also comparable between the groups (Table 2).

Long term follow up

The follow up could be completed in all 24 cases and was significant longer in the HW group (HW 112 ± 22 months; LW 75 ± 16 months).

In no case a hernia recurrence occurred. Two patients of the LW-group complained of low dragging pain during physical activity but no pain at rest (follow up 18 and 36 months respectively), whereas two patients of the HW-group reported on abdominal pain at rest as well as in motion (16.6%). One of these patients had a "stiff abdomen" (follow up 31 month), the other had no alteration of the abdominal wall mobility (follow up 89 month).

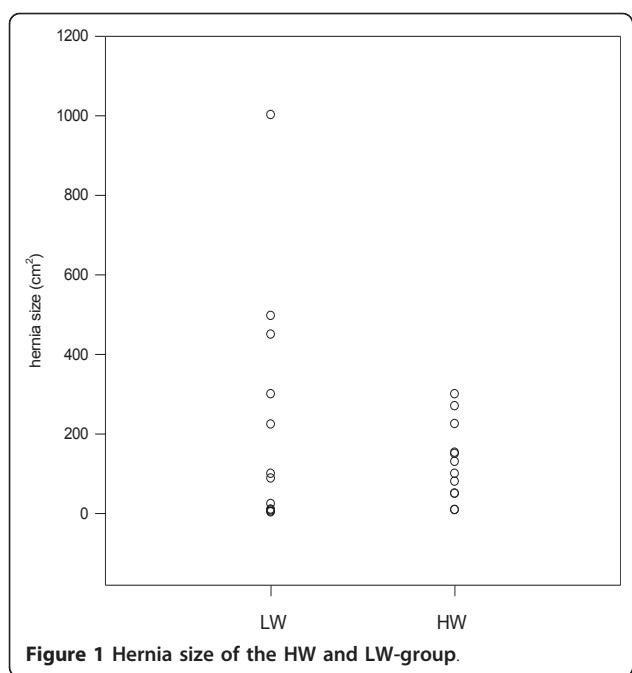

Figure 1 Hernia size of the HW and LW-group.

In these four patients (2 HW and 2 LW) ultrasound and MRI imaging studies were carried out. The polypropylene mesh was not visible in any of these cases. The abdominal wall in the patient with the "stiff abdomen" (HW group) showed a reduced mobility in the functional cine MRI study and an asymmetric fatty atrophy of the rectus muscle. In the other three patients (1 HW and 2 LW) no changes of the abdominal wall mobility or morphology could be detected. In all four patients intraabdominal adhesions could be identified, however these did not correlate with the mesh type.

Nevertheless in none of the eight domains of the SF 36 health survey a significant difference could be found. The SF36 Survey therefore showed no significant worse or better outcome for one mesh type in the long term follow up. The postoperative health-quality domains

Table 2 Comorbidities

back pain	1	-

were lower than the scores of the age-stratified healthy German population. (Table 3 and 4).

Discussion

PP is one of the most widely used meshes in abdominal wall surgery. It elicits an intense desmoplastic reaction in tissue, accompanied initially by serous exudation and resulting eventually in the formation of a sheet of scar that uses the mesh as a scaffold for its formation [7,14]. This mesh integration process in the abdominal wall and extent of scar tissue are regulated by the amount and structure of the incorporated material. The heavier the mesh weight and the smaller the size of the mesh pores are, the greater the resulting amount of scar tissue. The wound healing process causes a contraction of the mesh about 40% [15]. A high inflammatory activity as in the wake of a high amount of foreign material can increase this rate up to 90% [1]. Moreover the tissue reaction is not uniform but an individual patient depending factor [16].

The initial deployment of abdominal wall meshes developed meshes with small pore size and accordingly heavy weight. The clinical consequence was an impairment of the abdominal wall compliance: so 20-38% of the patients complained of reduced flexibility of the abdominal wall ("stiff abdomen") [3,4,17]. Since chronic pain has direct impact on most of the daily activities, it's an important aspect in the outcome of hernia surgery [18]. So the health related quality of life (HrQoL) has been receiving increasingly significance in the outcome evaluation of surgical treatments in the last years [19-26].

To reduce the incidence of abdominal stiffness and chronic pain, macropore light weight PP meshes strong enough to resist maximal physiologic stress of the abdominal wall were developed [5]. The aim of this study was to investigate whether the mesh type (LW vs HW) has an impact on the "quality of life" in the long term follow up (> 72 months) after incisional hernia repair. Hypothesis was that the use of LW meshes lead to less chronic pain and therefore to a better physical, psychosocial and social well-being compared to patients with HW-meshes.

Table 1 Demographic data

	LW mesh (Vypore®)	HW mesh (Prolene®)	p
number of patients	12	12	
sex ratio (male:female)	9:3	8:4	
age (year)	58.3 ± 11.1	57.3 ± 11.8	0.840
number of risk factors	1.8 ± 0.7	2.3 ± 1.2	0.318
BMI (kg/m ²)	28.7 ± 3.5	29.8 ± 3.7	0.462
hernia size (cm ²)	226.0 ± 301.5	127.2 ± 97.2	0.292
operation length (min)	105.0 ± 41.8	110.4 ± 23.5	0.699
hospital stay (d)	10.4 ± 3.8	6.8 ± 5.5	0.078

Data for the LW light weight and HW heavy weight group are presented as mean ± standard deviation. Differences were considered significant at p < 0.05.

Table 3 SF 36 health survey

	LW mesh (Vipro®)	HW mesh (Prolene®)	p	German normal population
physical functioning	64.2 ± 26.5	71.3 ± 33.3	0.570	83.7 ± 19.5
physical role functioning	50.0 ± 46.5	45.8 ± 45.0	0.826	80.6 ± 31.9
bodily pain	62.3 ± 35.0	67.3 ± 31.9	0.718	72.7 ± 27.3
general health perceptions	50.6 ± 26.5	49.3 ± 21.5	0.894	61.0 ± 19.1
vitality	48.3 ± 13.4	51.3 ± 10.3	0.555	61.2 ± 17.3
social role functioning	74.0 ± 22.9	70.8 ± 21.5	0.734	86.8 ± 18.0
emotional role functioning	47.2 ± 48.1	77.8 ± 32.8	0.084	88.9 ± 26.9
mental health	60.3 ± 29.3	70.3 ± 12.4	0.288	72.4 ± 16.1

The first four domains describe the physical, the last four the mental health status. The results from each scale vary from 0 to 100 (worst to best possible health status). The scores are compared to the age-stratified German population (Bullinger M, Kirchberger I. S36 Fragebogen zum Gesundheitszustand Holzgreve 1998) Data for the LW light weight and HW heavy weight group are presented as mean ± standard deviation. Differences were considered significant at p < 0.05.

As an instrument to investigate this question the SF-36 Health Survey was used. This is a well validated generic health status measure as opposed to one that targets a specific age disease or treatment group [10,27,28]. The questionnaire is made of up eight-scales. Four of them describe the physical and four the mental health status. The SF 36 Health Survey has been translated in more than 50 languages and adjusted to the cultural variations [24,29]. For hernia patients no specific HRQoL questionnaires are available.

In our study two patients of the LW-group complained about low dragging pain during physical activity. The pain did not persist at rest. Two patients of the HW-group reported on abdominal pain at rest as well as in motion (16.6%). The reported intensity of the pain was lower in the LW-group. However the SF36 Survey showed no significant difference in the quality of life of patients operated with a LW -or a HW -mesh in the long term follow up.

This lack of difference in the quality of life of the two groups is an interesting finding. In fact most studies investigating the life quality of patients undergoing inguinal hernia repair showed significant better results for LW meshes [30].

This is probably due to the fact that requirements for inguinal and ventral open hernia repair are different. The quality and the causes of pain following surgery are also different in inguinal and incisional hernia repair [31-33]. As a complication of inguinal hernia repair patients suffer mostly of neuropathic pain [32,34]. This

is due to nerve compression caused by nerve injury during surgery (suture, tacks, mesh) or by perineural fibrosis induced by the incorporated mesh. The key to avoid chronic neuropathic pain is the preservation of the nerves during surgery beside the choice of an appropriate mesh material [35].

After open incisional hernia repair dominates non neuropathic somatic pain, caused by mechanic pressure of the folded mesh or scar tissue. This pain condition is influenced by the mesh elastic properties and the amount and structure of the material used for repair [31-33]. The mesh type and structure are therefore the main reason for the abdominal wall compliance and pain in the postoperative period.

An explanation for the lack of difference in the quality of life of patients operated with a more elastic and lighter material compared to those operated with heavier and stiffer material might be that chronic pain did not have the expected influence on the daily activity of the patients.

Nikkolo et al arrived to a similar conclusion in a randomised trial comparing LW and HW meshes for inguinal hernia repair [36]. Also Conze et al found in a prospective randomized clinical trial comparing lightweight composite mesh with polyester or polypropylene mesh no difference in the SF 36 physical function scores or daily activity for the first 24 month after the operation. In this study the SF36 scores between 4 and 24 months showed no further improvement. These findings were also irrespective of the mesh type [37].

The mean age of patients undergoing incisional hernia repair was 57 ± 11 and 58 ± 11 years. The health perception changes with increasing age. So despite poorer role and physical function elderly patients have similar global health perception compared with younger individuals [38].

Another important aspect is that this study compares the quality of life following open incisional hernia repair after a longer period of time (112 ± 22 and 75 ± 16

Table 4 Physical and mental component summary

	LW mesh (Vipro®)	HW mesh (Prolene®)	German normal population
PCS	47.8 ± 7.5	49.4 ± 7.3	47.9 ± 9.7
MCS	46.6 ± 8.5	48.8 ± 10.0	51.16 ± 8.1

PCS (physical component summary) and MCS (mental component summary) in comparison to the age-stratified German population. (Bullinger M, Kirchberger I. S36 Fragebogen zum Gesundheitszustand Holzgreve 1998)

months) in opposition to most studies with a follow up of 6 to 12 months. Probably patients get used to the increased abdominal wall stiffness caused in the long term. However two patients of the heavy weight group complained of chronic pain as opposed to the low weight group where two patients complained of discomfort.

More generally the HrQoL of patients undergoing incisional hernia repair (no matter if with low or heavy weight mesh) is worse than that of the healthy population in the same age. There are several possible explanations for this. The comorbidities (cancer, heart disease, diabetes, back pain) might have influence on the quality of life. Some of those diseases or their treatments (diabetes, COPD, corticosteroid-/chemotherapy) are known to be risk factors for hernia formation. On the other hand patients with chronic disease tend to downscale their expectations for life and feel satisfied as long as they can stabilize their condition and be free from complication and aggravation [39].

The study has several limitations. First the group size is small. Starting with January 1998 heavy weight meshes were no longer used in our department. Additionally due to the long term follow up also the drop out rate was high. Therefore it was not possible to include more patients in this study. This reduces the power of the statistic.

Second limit is the different length of observation of the groups. However the shortest median observation time is 75 months. In our experience patients symptoms do not change significantly more than 5 years postoperatively.

Another limitation is the method of measuring the quality of life. A hernia specific scale would be preferable. Such a validated instrument though was not available at the time of the study and does not exist up to now in German language. For this reason the SF-36 was used.

Conclusions

In this study the health related quality of life based on the SF 36 survey after open incisional hernia repair with light or heavy weight meshes is not related to the mesh type in the long term follow up.
